A molecular gradient in early *Drosophila* embryos and its role in specifying the body pattern

Paul M. Macdonald* & Gary Struhl*

Department of Biochemistry and Molecular Biology, Harvard University, 7 Divinity Ave, Cambridge, Massachusetts 02138, USA

After fertilization, the protein products of the Drosophila *homeobox gene* caudal (cad) *accumulate in a concentration gradient spanning the anteroposterior axis of the developing embryo. Mutations in the* cad *gene that reduce or eliminate the gradient cause abnormal zygotic expression of at least one segmentation gene* (fushi tarazu) *and alter the global body pattern.*

ONE recurring dilemma in developmental biology is the conflict between mosaic models of embryonic patterning which invoke rigid localizations of qualitatively distinct determinants, and regulative models, which postulate morphogen gradients or inductive cascades of cell-cell interactions. In the case of insect development, the classic experiments of Sander[1-4] and others[5-9] have ruled out mosaic models, except possibly for the segregation of the germ line[10], and argued strongly for anteroposterior gradients of morphogens that specify the body pattern. Further support for such a gradient model has come from the analysis of maternal effect mutations, such as *bicaudal*, *oskar* and *bicoid*, which alter the global segment pattern[11-18]. But concrete demonstrations of graded morphogens have been frustratingly absent.

During the past few years, molecular studies have led to the identification of a conserved structural domain, the homeobox, common to many genes which control segment development[19,20]. In general, homeobox containing genes have tightly restricted spatial roles[21-25]; hence, they are first activated in specific regions of the embryo around the time segments are established[19,26-33]. Recently, we (unpublished observations) and others[34,35] have identified a new homeobox gene, *caudal* (*cad*)[34], which has the unusual property of being expressed during oogenesis and early embryogenesis. Hence, it seemed possible that this atypical gene might have a more global role in organizing the segment pattern. Indeed, circumstantial evidence for such a role has been obtained by Mlodzik *et al.*[34] and Levine *et al.*[35] who observed that *cad* transcripts form an anteroposterior concentration gradient during the syncytial blastoderm stage when the segment pattern is being set up.

We have used antibodies directed against the *cad* protein, together with mutations in the *cad* gene, to examine its develop-

---

mental role. We find that the *cad* protein is localized in nuclei and is distributed in an anteroposterior gradient throughout the embryo during most of the syncytial blastoderm stage. As observed for the *cad* messenger RNA[34,35], the *cad* protein gradient forms after fertilization, and disappears by the onset of gastrulation, when expression is restricted to a circumferential band of cells near the posterior pole. Further, we show that mutations which appear to inactivate the *cad* gene alter both segmentation and the expression of the pair-rule gene *fushi tarazu* (*ftz*)[36,26,27]. Thus we have directly visualized a graded gene product which acts in specifying the body pattern.

Establishment of a *cad* protein gradient

Rabbit polyclonal antibodies directed against the *cad* portion of a β-galactosidase-*cad* fusion protein (Fig. 1) were used to visualize the distribution of *cad* protein throughout embryogenesis as described (Figs 2 and 3).

During early *Drosophila* development, the single nucleus of the zygote undergoes a series of 13 largely synchronous divisions before cellularization (see refs 37, 38 for detailed descriptions; these divisions define fourteen stages numbered according to the nuclear division which completes each stage). Initially, the proliferating nuclei accumulate in the central, yolky portion of the egg. We detect little if any *cad* protein in the embryo during these early division cycles (stages 1-4); however, beginning in either stage 5 or 6, the cytoplasm and diffuse zones of 'structured cytoplasm'[38,39] around the nuclei stain faintly with the *cad* antibody (data not shown). During stage 7 most of the nuclei begin to migrate towards the periphery; nuclear migration continues during stage 8 and is complete by the end of stage 9 when peripheral nuclei at the posterior pole are incorporated into pole cells. In this period (stages 7-9), *cad* protein accumulates dramatically, especially in the posterior half of the body, forming a smooth concentration gradient along the anteroposterior axis (Fig. 2*a*; see also Fig. 2*b*). In addition, *cad* protein throughout the body becomes progressively more tightly localized to nuclei. The peripheral nuclei then undergo a further 4 rounds of syncytial divisions, during which time (stages 10-13), the concentration gradient persists and spans the length of the embryo (Fig. 2*b*, *c*, *d*). Note that graded nuclear expression of *cad* protein runs throughout the egg, including both peripheral and 'yolk' nuclei (Fig. 2*c*, *d*); posterior pole cell nuclei also stain intensely with the *cad* antibody.

Formation of the *cad* protein gradient does not depend either on nuclear division or zygotic gene expression. Unfertilized eggs collected within 90 minutes of laying show either no *cad* expression, or moderate, relatively uniform expression. In older unfertilized eggs, the levels of *cad* protein rise markedly, especially in the posterior portion of the egg, generating an anteroposterior gradient similar to that normally present in stage 9-13 embryos (data not shown).

Further polarization

Beginning in early stage 14, the pattern of *cad* protein distribution changes dramatically. Initially, antibody labelling subsides progressively from the anterior end of the embryo (Fig. 2*e*), while expression either persists or is enhanced in the posterior half. This results in a transient bipartite staining pattern in which the anterior 40% of the embryo appears devoid of *cad* protein, while relatively high levels of staining remain in the posterior 50%. The progressive loss of *cad* protein then continues into the posterior half of the embryo, extending more quickly along the ventral side (Fig. 2*f*, *g*). At the same time, *cad* protein levels decline in somatic nuclei at the posterior pole (between 0-13% egg length, EL, measured from the posterior pole) although not in the pole cells. These various changes in *cad* expression generate a diffuse posterior ring of *cad* protein which extends more anteriorly on the dorsal than the ventral side. Still later, as the blastoderm cellularizes and gastrulation ensues, this diffuse zone of expression sharpens into a discrete posterior

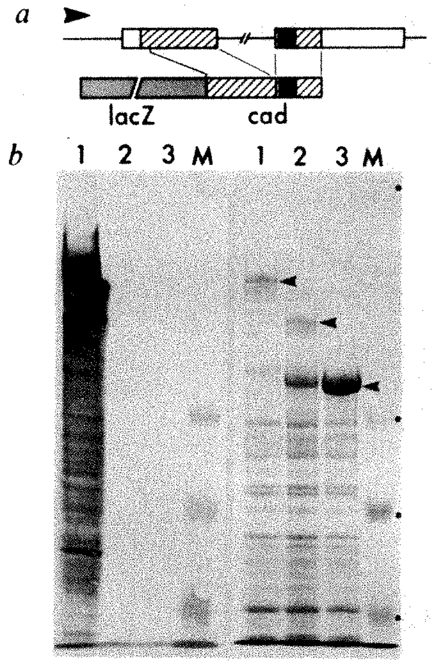

Fig. 1 Antibodies against the *cad* protein. *a*, Structure of the *cad* gene and derivation of a β-galactosidase-*cad* fusion protein. *b*, Specificity of the *cad* antibody. *a*, Zygotic and maternal transcripts of the *cad* gene are composed largely if not exclusively of two exons (wide bars) separated by an ~10 kilobase (kb) intervening sequence. Although the 5′ end of the first exon differs in the various maternal and zygotic transcripts, all have an identical long open reading frame. A 180-base-pair (bp) homeobox is positioned close to the splice junction in the second exon (ref. 34 and P.M.M., unpublished data; open boxes, untranslated 5′ and 3′ portions of the mature maternal transcript; hatched boxes, major open reading frame; black boxes, homeobox domain; arrowhead, direction of transcription). A *lacZ-cad* fusion gene (plc201) was constructed in the vector pUR290 (ref. 64) such that *cad* amino acids 29–425 (a total of 425 is predicted by the DNA sequence) were fused in frame to the carboxy terminus of β-galactosidase (the *cad* gene in p1c201 was derived almost entirely from genomic DNA except for a small segment covering the splice junction which was obtained from a cDNA clone; stippled box = the β-galactoasidase coding sequence). *b*, Total protein from IPTG-induced bacteria containing the *lacZ-cad* fusion gene plc201 (lane 1), a *lacZ-even-skipped* fusion gene including the *even-skipped* homeobox domain (lane 2) and the unfused *lacZ* gene from the fusion gene vector (pUR290) (lane 3) was separated by SDS-polyacrylamide gel electrophoresis, electroblotted onto nitrocellulose and probed with affinity-purified rabbit anti-*cad* antibodies prepared as described below (left panel). A duplicate gel stained with Coomassie Blue is shown in the right panel. No cross-reactivity to either β-galactosidase or homeodomain determinants is detectable. The heavy smear extending downward from the *cad* fusion protein bands in lane *C* is due to breakdown products of the unstable fusion protein. Size markers (highlighted by filled circles on the right) have relative molecular masses of 200,000 (M_r 200K) 97.4K, 68K and 43K.

Methods. The *cad* gene was cloned in a systematic screen[29] for new homeobox-containing genes, and the complete coding sequence of the gene determined directly (P.M.M., unpublished data). Positive confirmation that this gene is indeed the *cad* gene described by Mlodzik *et al.*[34] is as follows: (1) *in situ* hybridization experiments show that it is located in the 38E5,6 polytene band interval of salivary gland chromosomes, (2) it generates maternal and zygotic transcripts with sizes and temporal profiles similar to those described[34], (3) the DNA sequence is virtually identical to the partial *cad* cDNA sequence published previously[34]. A *lacZ-cad* fusion gene (plc201) was constructed as described in *a*. After IPTG induction of E. coli strain 71-18 (ref. 64) carrying plc201, the fusion protein was partially purified by preparative SDS-polyacrylamide gel electrophoresis, homogenized in Freunds complete adjuvant and injected subcutaneously at multiple sites in virgin female rabbits. Booster immunizations (in Freunds incomplete adjuvant) were given 2 months later, and serum collected after a further 10 days. Contaminating antibodies directed against β-galactosidase, other *E. coli* proteins, and generic homeodomain determinants were removed by successive passages over affinity columns prepared by coupling the desired ligand to Affigel 10 (Biorad). Ligands used were purified β-galactosidase (BRL), or a crude bacterial extract from cells containing a *lacZ-even-skipped* fusion gene (pleBB1, which includes the *even-skipped* homeobox). A similar column, prepared from the plc201 bacterial extract, was used for affinity purification of the anti-*cad* antibodies. Detailed descriptions of plasmid constructions and antibody purification are available upon request. The Western blot was prepared and stained by standard methods, using an NTB/BCIP alkaline phosphatase detection system (BRL).

ring 3-4 cells wide (Fig. 2*h*; a dorsal stripe of labelling sometimes persists transiently at around 50-60% EL). Note that throughout this process, the changes in *cad* distribution in the peripheral and yolk nuclei are tightly coordinated until the posterior ring is well defined, at which time the yolk nuclei stain poorly or not at all.

Expression of *cad* in subsequent development

At the onset of gastrulation, the presumptive mesoderm, including cells from the most ventral portion of the *cad* posterior ring, invaginate through the ventral furrow; soon thereafter, the pole cells, which continue to label with the *cad* antibody, begin migrating dorsally and anteriorly, surrounded by the remaining cells of the posterior ring. As the germ band extends, the pole cells and possibly some cells from the posterior ring appear to enter the posterior mid-gut invagination (Fig. 2*i*). Subsequently, cells in the developing posterior mid-gut and malpighian tubules (but not in the hindgut) express high levels of *cad* protein. The *cad* staining cells which remain on the outside of the embryo form a segment-length block of cells in the posterior germ band, which ultimately gives rise to parts of the larval anal pads (Fig. 2*j*). Based on double-labelling experiments with a monoclonal antibody directed against *Ultrabithorax* protein products[40], this block of cells appears to lie immediately posterior to parasegment 14 (see ref. 41) and may thus correspond to a cryptic fifteenth parasegment (data not shown).

Three additional features of *cad* expression are notable. First, in favourable preparations of embryos during germ band extension, we observe six narrow stripes of cells positioned at double segment length intervals (Fig. 2*i*). Second, a few bilaterally symmetric pairs of neurons are labelled in the neuromeres of parasegments 1-14 (ref. 42) after germ band shortening (later this labelling is retained in only two to four neuromeres in the thorax and anterior abdomen; Fig. 2*j*). In addition, a small cluster of neuroblasts perhaps belonging to a cryptic fifteenth parasegment labels at the posterior end of the nerve cord (data not shown). Third, persistent *cad* labelling is also observed during the remainder of larval development and in adults in the posterior mid-gut, malpighian tubules, and portions of the genital imaginal disc from which the adult analia may be derived (Fig. 2*j* and data not shown).

Mitotic cycle dependence

The large size and mitotic synchrony of the peripheral nuclei in the syncytial blastoderm stages allow us to monitor the presence and subnuclear distribution of the *cad* antigen throughout the mitotic cycle. As shown in Fig. 3*e*, the *cad* antibody does not label interphase nuclei uniformly, but rather reveals a punctate distribution of *cad* protein which is similar to, although not coincident with, that of AT rich satellite DNA (as revealed by the Hoechst stain which labels DNA in proportion to its AT-content[43]). In contrast, a monoclonal antibody, 8C5, which appears to recognize a ubiquitous chromosomal antigen[70] displays a more uniform and diffuse staining pattern (Fig. 3*f*).

At the onset of mitosis, nuclear *cad* labelling disappears almost completely (as previously noted for *engrailed* protein[44]), although both the Hoechst stain and the 8C5 antibody clearly label condensed chromosomes (Fig. 3*a-c*). Because the level of diffuse cytoplasmic staining seems to rise during this period, it is possible that the *cad* protein is actually displaced from condensed chromosomes rather than being rendered inaccessible to the antibody. By late telophase, nuclei begin to label again with the *cad* antibody, although punctuate staining is not evident until interphase.

These observations suggest that *cad* protein may be associated with discrete chromosomal sites during interphase (when transcription occurs) and that these sites may be closely linked or brought close together within the nucleus. Also, they suggest the possibility that *cad* protein may be displaced from the chromosomes during mitosis.

Mutations in *cad* alter segment specification

Four recessive mutations of the *cad* gene have been obtained using EMS mutagenesis ($cad^{1,2,3,4}$; see Fig. 4). Three of these four mutations ($cad^{2,3,4}$), as well as deletions[45] of the *cad* gene region, cause recessive lethality and eliminate detectable levels of *cad* protein in the diffuse posterior ring and later embryonic derivatives where *cad* is normally expressed (for example, Fig. 2*i, j*). They therefore behave as apparent null alleles and are referred to subsequently as cad^- mutations.

Homozygous cad^- embryos obtained from heterozygous mothers give rise to almost normal first instar larvae. However, these larvae lack cuticular structures of the posterior terminalia, most notably the anal tuft, parts of the anal pads, and the terminal sense organs[24] (sense organs 1 in ref. 46), all structures supposed to derive from a cryptic tenth abdominal segment[46] (or parasegment 15) (Fig. 4*d*). Thus embryos receiving maternally derived gene product, but lacking a functioning *cad* gene, form a normal segment pattern except for terminal structures derived from cells which display persistent zygotic *cad* expression.

When embryos derived from $cad^-/+$ parents are stained for expression of the *cad* gene product, all embryos before stage 14 show the characteristic patterns of *cad* protein, even though $\frac{1}{4}$ should be homozygous for the cad^- mutation. Thus, normal graded patterns of *cad* protein can be generated from maternally derived products of the *cad* gene, without any zygotic contribution. To examine the consequences of lacking *cad* gene function during this early period of embryogenesis, it is therefore neccessary to eliminate both the maternal and zygotic contributions. This has been done by generating clones of homozygous cad^- germ cells by gamma-ray induced mitotic recombination in $cad^-/+$ larvae (as in ref. 47), and then fertilizing eggs derived from such mutant germ line cells with cad^- sperm (see Fig. 5).

After fertilization of mutant cad^- eggs with sperm from $cad^-/+$ males, two classes of progeny were obtained in approximately equal numbers. The first class give rise to first instar larvae which usually hatched and often developed into normal fertile adults. However, many of these larvae were found to lack portions of the eighth abdominal segment (Fig. 4*c*); less frequently they also showed partial deletions of the fourth abdominal segment, and on occasion, of other, usually even-numbered, abdominal segments. These larvae almost certainly derived from mutant eggs fertilized by wild type sperm, because all of the progeny obtained from mutant eggs fertilized by wild type males developed in this fashion. Thus, even in the absence of maternally derived cad^+ function, zygotic expression from a single, paternally derived cad^+ gene is sufficient to allow normal, or almost normal, development.

Progeny of the second class show a dramatic alteration of the normal body pattern and presumably arise from fertilization of mutant eggs by mutant sperm (Fig. 4e-h). Although the segmentation phenotypes of these larvae are variable both from animal to animal, and between the left and right sides of single animals, certain common features emerge. First, the head and anterior thorax are usually normal, while the remainder of the body is severely shortened owing to variable deletions of many of the posterior segments. In general the second thoracic and odd-numbered abdominal segments are more resistant to deletion, so that most larvae show a phenotype resembling that of alternating segmental deletions caused by mutations in 'pair-rule' segmentation genes[48]. Second, most of the eighth abdominal segment and posterior terminalia (although curiously not some portions of the posterior spiracles) are absent and replaced by small plates of sclerotized cuticle resembling mouth-hooks. In addition small clusters of very fine ventral hairs (usually characteristic of the patch of ventral hairs in the middle of the prothorax) lie between these plates and the preceding

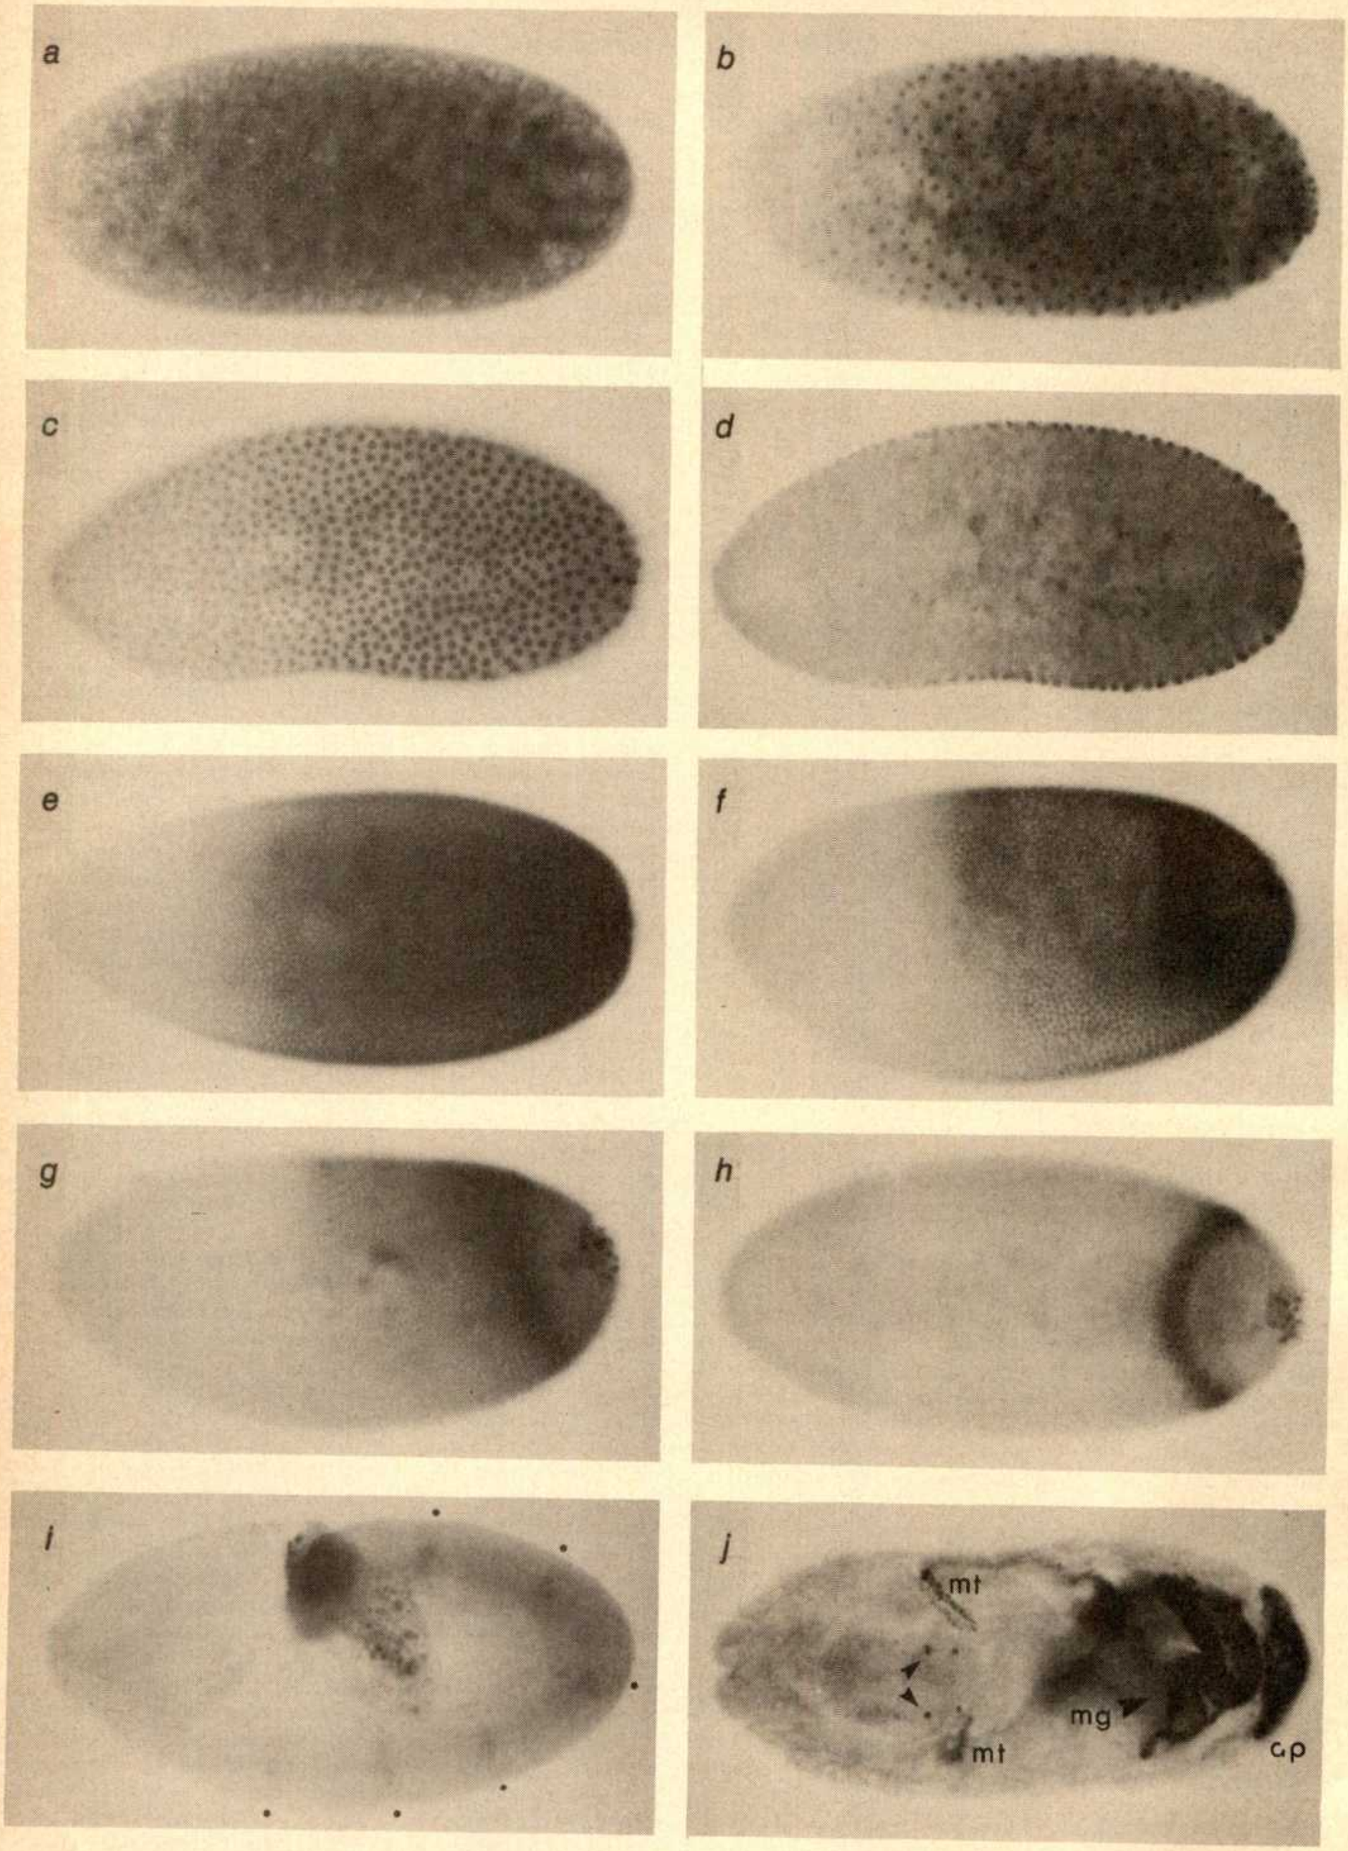

Fig. 2 (legend opposite).

Fig. 2 Immunohistochemical localization of *cad* protein during embryogenesis. All embryos are oriented with anterior to the left and the plane of focus through the middle of the embryo (*a, d, i, j*) or at the periphery (*b, c, e, f, g, h*); embryos before gastrulation are staged according to the nuclear division cycle (for instance, stage 9 falls between the 8th and 9th nuclear divisions). *a*, Stage 8 embryo. All of the nuclei are still located within the central yolky region of the egg. Staining with the *cad* antibody is most intense in the nuclei, but note that islands of cytoplasmic staining surround each nucleus. Graded distribution of the *cad* protein is already apparent, as displayed by the gradual reduction of staining towards the anterior pole. *b*, Stage 10; Nuclear migration to the periphery is complete and the pole cells have budded off. The *cad* protein gradient now extends along the entire body axis, peaking at the posterior pole. This pole to pole concentration gradient is maintained until the beginning of stage 14. Note that it is unlikely to be due to either a fixation artifact or unequal accessibility of the antibody, as both the DNA dye Hoechst 33258 as well as a monoclonal antibody directed against a chromosomal antigen reveal uniform staining throughout this period in triple labelling immunofluorescent experiments (see Fig. 3); the close to uniform distribution of *cad* protein observed in *BicD* embryos (Fig. 5a) also argues against such possibilities. *c, d*, Stage 12 (periphery and inside respectively). The *cad* gradient is confined predominantly to nuclei and is apparent both in peripheral and yolk nuclei. Pole cell nuclei, just visible in *d*, stain as intensely as the neighboring somatic nuclei. *e*, Early stage 14. During stage 14 the distribution of *cad* protein undergoes a dramatic change, becoming progressively more polarized until it is restricted to a single posterior ring 3–4 cells wide at the onset of gastrulation. This embryo shows the early phase of the redistribution in which *cad* protein is removed progressively from the anterior pole. *f*, Early-mid stage 14 (dorsal side at top). Progressive loss of *cad* staining continues extending more quickly along the ventral surface; staining also begins to decline in somatic nuclei between 0–13% egg length (EL; from the posterior pole). Thus, *cad* staining now appears predominantly in a diffuse posterior ring which extends dorsally to about 55% EL. *g*, Mid-stage 14 (dorsal side at top). *cad* staining continues to decline from the anterior and dorsal directions, although intense staining persists in the posterior ring (now somewhat narrower) and in the pole cells. Note that the anterior dorsal boundary of *cad* labelling remains quite distinct, despite the falling level of expression. Note also that here, as in *f*, *cad* expression in the yolk nuclei (out of focus, but visible as dark spots in the center of the embryo) parallels that of the peripheral nuclei, declining progressively in the anterior and ventral portions of the egg. *h*, Late stage 14 (dorsal surface). By the onset of gastrulation, *cad* protein is found in a tightly restricted posterior ring (which is ~3–4 cells wide around the entire embryo) and in the pole cell nuclei. In some preparations, a relatively faint dorsal stripe 1–2 cells wide can be seen anterior to the posterior ring. *i*, Germ band extension (lateral aspect). As the germ band extends dorsally and anteriorly, most *cad* expressing cells from the posterior ring remain at the terminus of the germ band, though some may enter the posterior midgut invagination together with the labelled pole cells. Transient *cad* expression is detected in rows of cells (●) which transect the elongating germ band, spaced at approximately double segment intervals from the block of *cad* staining cells at the end of the germ band. *j*, 15 h embryo (ventral aspect). The *cad* staining can be seen in cells giving rise to portions of the anal pads (*ap*), the posterior midgut (*mg*), and the malpighian tubules (*mt*) which wander in and out of the plane of focus. Staining is also apparent in one or more pairs of bilaterally symmetric nuclei in several neuromeres (arrow heads). Similar neuroblast staining is seen in most if not all of the neuromeres at an earlier stage (after germ band shortening), but is restricted to only a few thoracic or anterior abdominal neuromeres as embryogenesis continues.
Methods. Embryos aged for 0–15 h after fertilization were dechorionated, fixed, devitellinezed, and incubated with the primary antibody as described previously[65,27,44]. The embryos were washed under standard conditions, and incubated with a goat anti-rabbit IgG secondary antibody coupled to biotin (Vector Labs) which had been preadsorbed with 0–12 h embryos. The embryos were then washed again and incubated with a streptavidin-horseradish peroxidase conjugate (BRL). After further washing, the histochemical stain was developed with hydrogen peroxide and diamino-benzidine to yield a permanent signal. Stained embryos were dehydrated in 100% ethanol and mounted directly in a mixture of ~1.5 g ml^{-1} dried canada balsam in methyl salicylate[66]. Preadsorption of the *cad* antibodies with the *cad* affinity resin (see Fig. 1 legend) eliminated the staining patterns shown here.

abdominal segment (usually A7). Note that, despite the severity of the segmental deletions, the overall polarity of cuticular derivatives such as ventral and dorsal hairs is usually unaffected.

Thus, complete absence of the *cad* gene function dramatically alters the normal segment pattern. In parallel with the polarized distributions of *cad* gene product during the syncytial blastoderm stage, anterior head and thoracic segments are usually unaffected, whereas more posterior portions of the body show progressively more severe defects.

Maternal versus zygotic contributions

The extreme segmental defects displayed by *cad*$^-$ mutant embryos can be rescued either by maternal or zygotic activity alone. Consequently, common features of maternal and zygotic

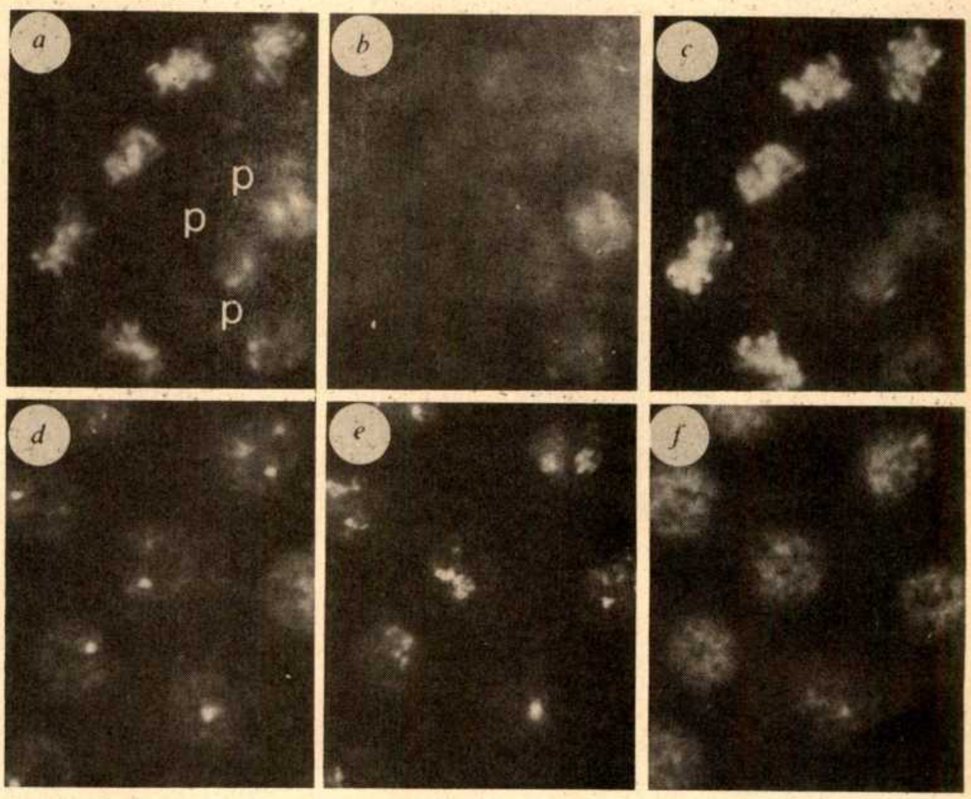

Fig. 3 Mitotic cycle dependence and subnuclear distribution of *cad* staining. The relative distributions of DNA, *cad* protein, and a chromosomal antigen recognized by the monoclonal antibody 8C5 (ref. 70) are shown during the 12th mitotic division (*a*, *b* and *c*, respectively) and during the interphase preceding this division (*d*, *e* and *f*). In both bases, the nuclei were located close to the posterior pole (indeed, in *a*, *b* and *c* the interphase nuclei of three pole cells (*p*) are adjacent to the mitosing syncytial nuclei). Note that the Hoechst stain (*a*) and 8C5 antibody (*c*) clearly show condensed chromosomes in mitosing peripheral nuclei, whereas only faint labelling is detected with the *cad* antibody (*b*). In contrast, interphase peripheral nuclei (*d*, *e*, *f*) as well as interphase pole cell nuclei (*a*, *b*, *c*) show punctate staining with both the Hoechst stain (*a*, *d*) and *cad* antibody (*b*, *e*) and a more diffuse pattern of staining with the 8C5 antibody (*c*, *f*). Note that the punctate pattern of the Hoechst stain (presumably labelling AT-rich satellite sequences[43]) does not coincide with that revealed by the *cad* antibody.
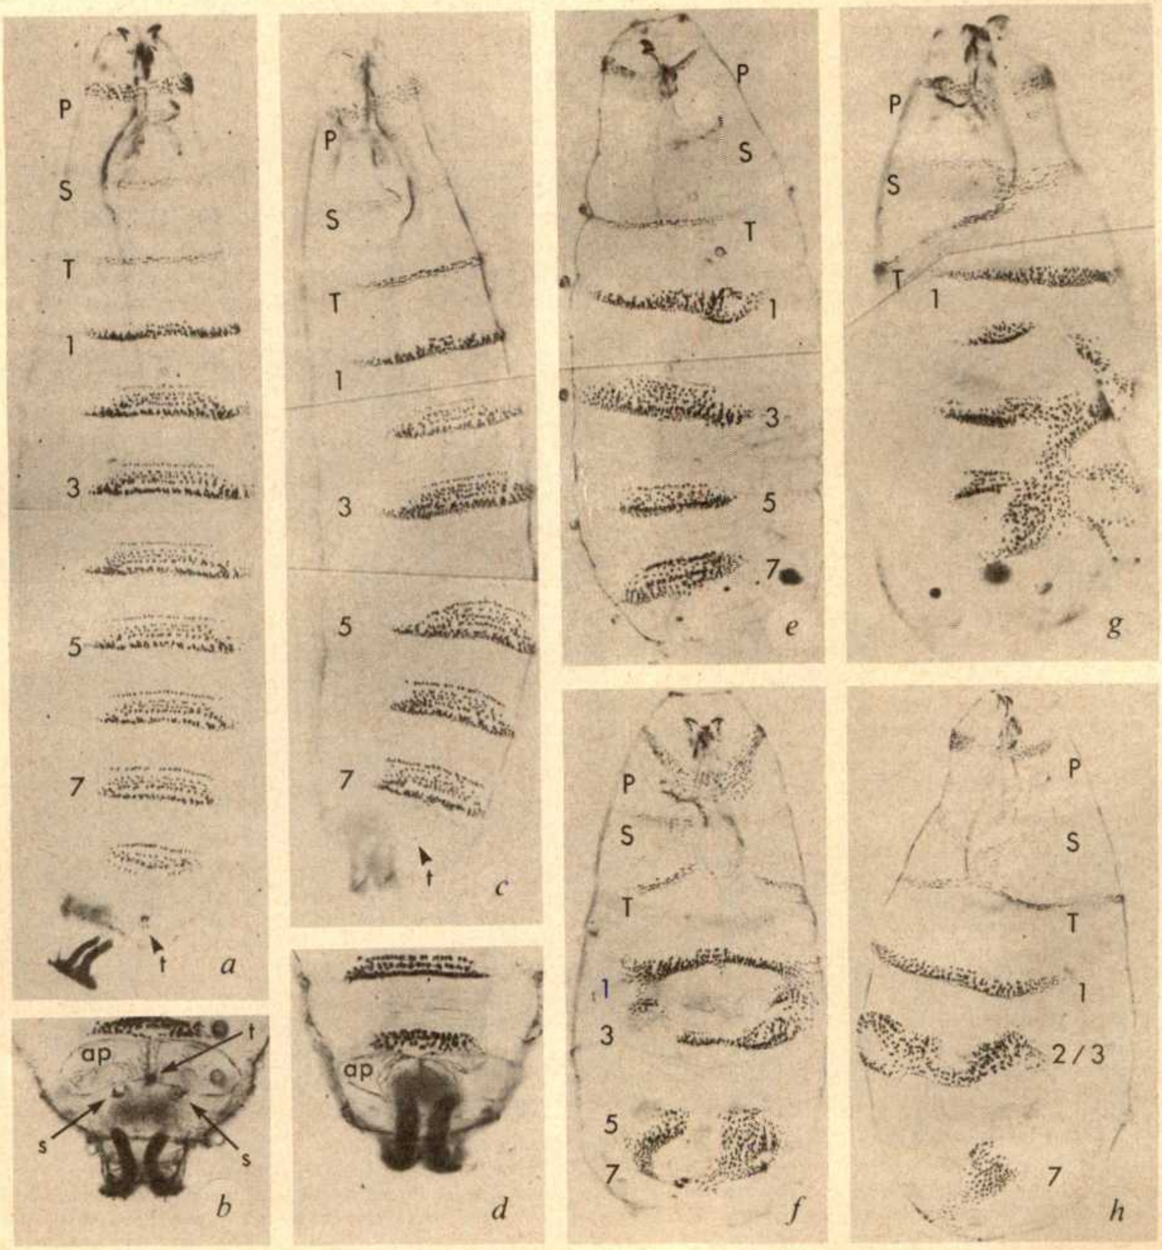
Methods. Embryos were prepared as in Fig. 2 and probed with the rabbit anti-*cad* antibody as well as the mouse monoclonal antibody 8C5. After washing, the embryos were incubated with two secondary antibodies, a preadsorbed goat anti-rabbit immunoglobulin G (IgG) coupled to biotin (Vector) and a goat anti-mouse IgG coupled to rhodamine (Tago Labs). The embryos were then washed again and incubated with a fluorescein-avidin conjugate (Vector Labs), stained with the Hoechst dye, washed, mounted in 50% glycerol with 2.5 mg ml^{-1} p-phenylenediamine added as an anti-bleaching agent, and examined with epi-fluorescence illumination.

protein expression may define critical aspects of *cad* function which are responsible for ensuring normal segmentation. As described above, all embryos derived from *cad*$^-$/+ embryos show normal graded patterns of *cad* protein until the beginning of stage 14. But after this time ~$\frac{1}{4}$ fail to show the normal bipartite pattern of expression or the subsequent polarization which gives rise to the posterior ring. Instead, embryos in this novel class display a gradually fading gradient of *cad* protein, although pole cells continue to stain intensely well into gastrulation (Fig. 5*d*; compare with Fig. 2*g*). Paternally rescued embryos (*cad*$^-$/+ embryos derived by fertilizing *cad*$^-$ eggs with wild type sperm) resemble maternally rescued *cad*$^-$ embryos in forming an anteroposterior gradient of *cad* protein, although the levels of *cad* expression are atypically low, close to the limit of detection (data not shown). In stage 14, the level of *cad* antigen rises significantly in posterior portions of paternally rescued embryos, forming the normal bipartite pattern (Fig. 5*e*) and then becoming progressively restricted to the posterior ring (as in Fig. 2*e*–*h*; note that no *cad* protein is expressed in pole cells).

Thus, the common link between the maternal and zygotic contributions to *cad* protein expression appears to be an anteroposterior differential in protein concentration which arises during the syncytial blastoderm stage. This can be generated solely by gradients of maternally derived gene product, or by graded and then more polarized patterns of zygotic expression.

Symmetrical *cad* expression in embryos

If the gradient of *cad* protein plays an instructive role in specifying the body pattern, mutations which cause global changes in the body plan should alter segmentation and the distribution of *cad* protein in a tightly coordinated fashion. Dominant mutations of the *BicD* locus act during oogenesis to alter the axial polarity of the early embryo[15]. Specifically, embryos derived from mutant mothers display a 'double abdomen' phenotype in which the body is composed of two sets of posterior abdominal segments and terminalia arranged in mirror symmetry[15]. When embryos from mothers transheterozygous for two dominant *BicD* mutations (see Fig. 5, legend) are stained with the *cad* antibody, they show corresponding alterations in the normal patterns of *cad* expression. First, in most embryos, *cad* antigen is distributed almost uniformly in nuclei throughout the body until early stage 14 (Fig. 5*a*). The intensity of labelling then



declines in the central portion of the embryo as well as in narrow zones at both ends (Fig. 5*b*). Finally, these embryos display a stable pattern of mirror symmetric posterior rings (Fig. 5*c*). These results show that *BicD* mutations cause a reorganization of the *cad* protein distribution which parallels that of the body pattern.

Expression of *fushi tarazu* in *cad*⁻ embryos

The tendency of *cad*⁻ mutant embryos to show pair-rule segmentation defects in the posterior half of the body suggests that one role of early *cad* protein activity may be to coordinate periodic expression of pair-rule genes[48] along the anteroposterior body axis. We therefore examined the expression pattern of the pair-rule gene *fushi tarazu* (*ftz*)[36,26,27] in cad⁻ embryos using a polyclonal antibody directed against the *ftz* protein (ref. 27). In wild type embryos, the *ftz* protein is expressed in 7 stripes of blastoderm nuclei shortly before the onset of gastrulation: the first six stripes are of equal width (3-4 nuclei) whereas the posterior seventh stripe is wider (5-7 nuclei)[27]. When *cad*⁻ eggs were fertilized by sperm from *cad*⁻/+ males, and the resulting embryos stained for *ftz* protein expression at the onset of gastrulation, two classes of progeny were observed in similar numbers. Embryos of the first class almost certainly correspond to paternally rescued *cad*⁻/+ embryos and approximate wild type *ftz* expression, although stripes 2 and 4 are slightly wider, and stripes 3, 5 and 6 slightly narrower than normal (Fig. 6*a*). In contrast, embryos of the second class almost certainly correspond to homozygous *cad*⁻ embryos and show highly variable and abnormal patterns of *ftz* expression, stripes 2 and especially 4 being much wider than in wild type embryos, and stripes 3, 5, 6 and 7 being much narrower or absent (Fig. 6*b*). Thus, absence of *cad* protein activity early in embryogenesis causes abnormal periodic expression of the *ftz* protein.

Discussion

Both embryological[1-9,49-52] and genetic[11-18] experiments provide compelling evidence that the segment pattern of the insect body is specified by a dynamic system of spatial cues generated early in development. Moreover, they have led to explicit proposals that this system consists of one or more morphogen gradients organized by the spreading influences of determinants at the anterior and posterior poles[2,17,18,53]. Here, we visualize a protein gradient which arises during the period when the body plan is established. Moreover, we show that the formation of this gradient depends on maternal factors such as the *BicD* gene[15] which influence the localization of anterior and posterior polar determinants[17,18]. Finally, we demonstrate that activity of the gradient protein is critical for setting up the normal segment pattern. Thus, we believe we have identified a graded morphogen which responds to early spatial cues and participates in organizing the body plan.

Role of the *cad* protein gradient

The developing pattern of *cad* protein expression is complex, involving first the accumulation of *cad* protein in the form of a continuous anteroposterior gradient, followed by progressive loss of the protein from the anterior pole until it is restricted to a ring of cells close to the posterior pole. Hence, the morphogenic role of the *cad* gene product could depend on the concentration gradient *per se*, or more simply, on the consequent generation of an anteroposterior differential of *cad* protein activity. Two lines of evidence support the view that graded *cad* expression *per se* is required for normal segmentation. First, embryos lacking the *cad* function show a spectrum of graded segmental defects which appear to correlate with the graded expression of *cad* protein during the syncytial blastoderm stage. Hence, the requirement for *cad* function appears proportional to the relative levels of protein along the body. Second, early graded expression of maternally derived gene product is sufficient to rescue the development of *cad*⁻ zygotes (except for derivatives of the posterior terminalia which require persistent zygotic expression). Neither line of evidence is compelling, however. Indeed, we also observe that zygotic expression, which generates first an abnormally shallow gradient, and then a more normal bipartite distribution can largely rescue the *cad*⁻ mutant phenotype. This last result argues against attaching a critical significance to the absolute concentration of *cad* protein along

Fig. 4 Segmental phenotypes resulting from loss of *cad* gene function. Four recessive mutations of the *cad* gene (*cad*^{1,2,3,4}) were obtained after EMS mutagenesis and the phenotypes of embryos lacking either maternal gene function (*c*), zygotic gene function (*d*), or both (*e–h*) have been determined as described below. Micrographs show the ventral cuticle patterns of first instar larvae (dark field illumination); the ventral dentical bands associated with the pro- (*P*), meso- (*S*) and metathorax (*T*) and the odd numbered abdominal segments (1, 3, 5, 7) are labelled; t, anal tuft (a patch of ventral denticals positioned just posterior to the anal pads); *a*, wild type; *b*, wild type posterior terminalia. Note the bilaterally symmetric anal pads (ap), the anal tuft (t) and the terminal sense organs (s) which lie just posterior and to either side of the tuft. *c*, paternally rescued *cad*^{2}/+ larva derived from a homozygous *cad*^{2} oocyte. Note the absence of the dentical bands associated with abdominal segments 4 and 8; neither segment is entirely deleted, as dorsal structures from both segments (not visible here) remain. *d*, Posterior portion of a homozygous *cad*^{3} larva derived from *cad*^{3}/+ parents. Larvae of this genotype are generally normal except for the absence of the anal tuft and portions of the anal pads. The terminal sense organs also appear to be absent or malformed. *e–h*, *cad*^{2}/*cad*^{3} larvae derived from homozygous *cad*^{2} oocytes. In general, embryos of this genotype usually form normal heads, part or all of the prothorax, and then a spectrum of progressively more extreme segmental deletions along the anteroposterior axis. As described in the text, an 'even-skipped' pair-rule modulation is often apparent (as in *e* and *f*), though more extreme deletions (*h*) or left-right differences in segmental deletions (*g*) can obscure this aspect of the phenotype. The polarity of cuticular structures within each segment is usually normal, though local perturbations are sometimes present in embryos such as *g*.

Methods. The *cad* gene maps to the polytene band interval 38E5,6 as determined by *in situ* hybridization experiments (ref. 34 and our unpublished data), a region which is deleted by a number of well characterized chromosomal deficiencies[45,67]. Two of these deficiencies, *Df(2L)TW1* and *Df(2L)TW2*, overlap, deleting a common region containing polytene bands 38A7-B1-38E6-E9 (ref. 45); a third deficiency, *Df(2L)Sd*^{R68} (37A/B-38E2-E5; ref. 67), deletes much of this common region, but not the 38E5,6 interval (we have confirmed these chromosomal assignments by determining that the *Df(2L)Sd*^{R68} chromosome, but not the *Df(2L)TW1* or *Df(2L)TW2* chromosomes can generate *cad* gene transcripts (P.M.M., unpublished data). We therefore performed a standard F2 screen of ~4,000 chromosomes for EMS-induced mutations which cause partial or complete lethality when *in trans* to *Df(2L)TW2*. All mutations were then retested against the remaining two deletions to eliminate most of the non-*cad* mutations. Of the remaining 30 mutations, 4 fall into a single complementation group which appears to define the *cad* gene by the following criteria: (1) all four mutations specifically cause loss of larval or adult structures which derive from embryonic or larval cells showing persistent zygotic expression of the *cad* protein; (2) approximately $\frac{1}{4}$ of the embryos generated by flies heterozygous for the *cad*^{2}, *cad*^{3} or *cad*^{4} mutations show no *cad* protein attributable to zygotic expression of the *cad* gene (as is observed for progeny from *Df(2L)TW1*/+ and *Df(2L)TW2*/+ parents), and (3) *cad*^{2}/+ embryos derived from *cad*^{2}/*cad*^{2} oocytes express *cad* protein during the syncytial blastoderm stage and in all subsequent stages, whereas *cad*^{2}/*cad*^{3} embryos derived from *cad*^{2}/*cad*^{2} oocytes do not express *cad* antigen at any time (*cad*^{1} homo- or hemizygotes express *cad* antigen, but are also able to survive to adulthood, generating male and female flies lacking anal plates; consequently, this mutation is likely to reduce rather than eliminate *cad* gene function). Finally note that although the three apparent null mutations of *cad* eliminate detectable *cad* protein expression, they may nevertheless retain low levels of *cad* protein activity and hence not be true amorphic mutations. Germ line clones of homozygous *cad*^{2} and *cad*^{3} cells were generated by standard means (see, for example ref. 47) using a dominant female sterile mutation, *Fs(2)1* (courtesy of Janos Szabad and Trudi Schupbach). Briefly, *b pr cad*^{2}/*Fs(2)1* (or *b pr cad*^{3}/*Fs(2)1*) larvae were γ-irradiated during the first instar and the resulting adult females crossed to *b pr cad*^{3}/*CyO, pr* (or *b pr cad*^{2}/*CyO, pr*) males. *Fs(2)1*/+ female germ cells either give rise to woefully abnormal eggs or no eggs at all; however, homozygous *Fs(2)1*$^+$ germ cells resulting from mitotic recombination proximal to the *Fs(2)1* mutation form normal eggs. Individual females laying normal eggs were selected and their progeny examined. Most (~90%) of these females generated the two classes of progeny described in the text, indicating that most recombination events that occur proximal to the *Fs(2)1* gene also occur proximal to the *cad* gene. Moreover, the paternally rescued (*b pr cad*⁻/*CyO, pr*) progeny from these females often survived to adulthood and were invariably purple in phenotype, confirming that they resulted from proximal mitotic recombination events (the remaining few females laying normal eggs generally gave rise to curly-winged progeny which had phentoypically wild type or purple eyes, indicating that mitotic recombination had occurred proximal to the *Fs(2)1* gene, but distal to the tightly linked *cad* and *pr* genes). Mutant larvae were dechorionated and dissected, when necessary, and mounted directly in a 1:1 mixture of lactic acid and Hoyer's mountant[68,69].

the body, and suggests that a coarse anteroposterior differential in *cad* function is required for normal segmentation.

Irrespective of which component of early *cad* expression is responsible for its morphogenic function, it is plausible that *cad* serves as a molecular link between more primary spatial determinants and the localized expression of zygotic control functions. For example, graded or differential expression of *cad* protein might be responsible for regulating the spatial expression of particular gap genes such as *hunchback*, *Kruppel* and *knirps*[46] which would then establish the segment pattern via the correct activation of pair-rule and homeotic genes[54-56]. Alternatively, graded *cad* expression might directly influence pair-rule and homeotic gene functions, some of which normally display anteroposterior gradients in their spatial expression[28,29,57,58]. Our demonstration that *cad*$^{-}$ embryos alter both segmentation and the periodic expression of the pair-rule gene *ftz* over a large region of the body provide direct support for the view that *cad* protein regulates the expression of pair-rule and homeotic genes either directly or via its effects on particular gap genes. The presence of a homeobox domain within the *cad* protein and our finding that *cad* protein is preferentially localized in transcriptionally active interphase nuclei both support this interpretation.

Generation of the *cad* protein gradient

If, as we propose, the dynamic pattern of *cad* expression is a response to the influence of more primary polar determinants, the mechanism by which the *cad* protein gradient forms is likely to be of considerable interest. One striking feature of our results is that *cad* protein expression appears to be graded both in peripheral and yolk nuclei and shifts posteriorly in these two populations of nuclei in a tightly coordinated fashion. Thus, as suggested previously by the initial pattern of activation of the segmentation gene *Kruppel*[59], the generation and interpretation of graded spatial information in insect embryos need not be a special attribute of the peripheral egg cortex, but may occur uniformly throughout the egg cell.

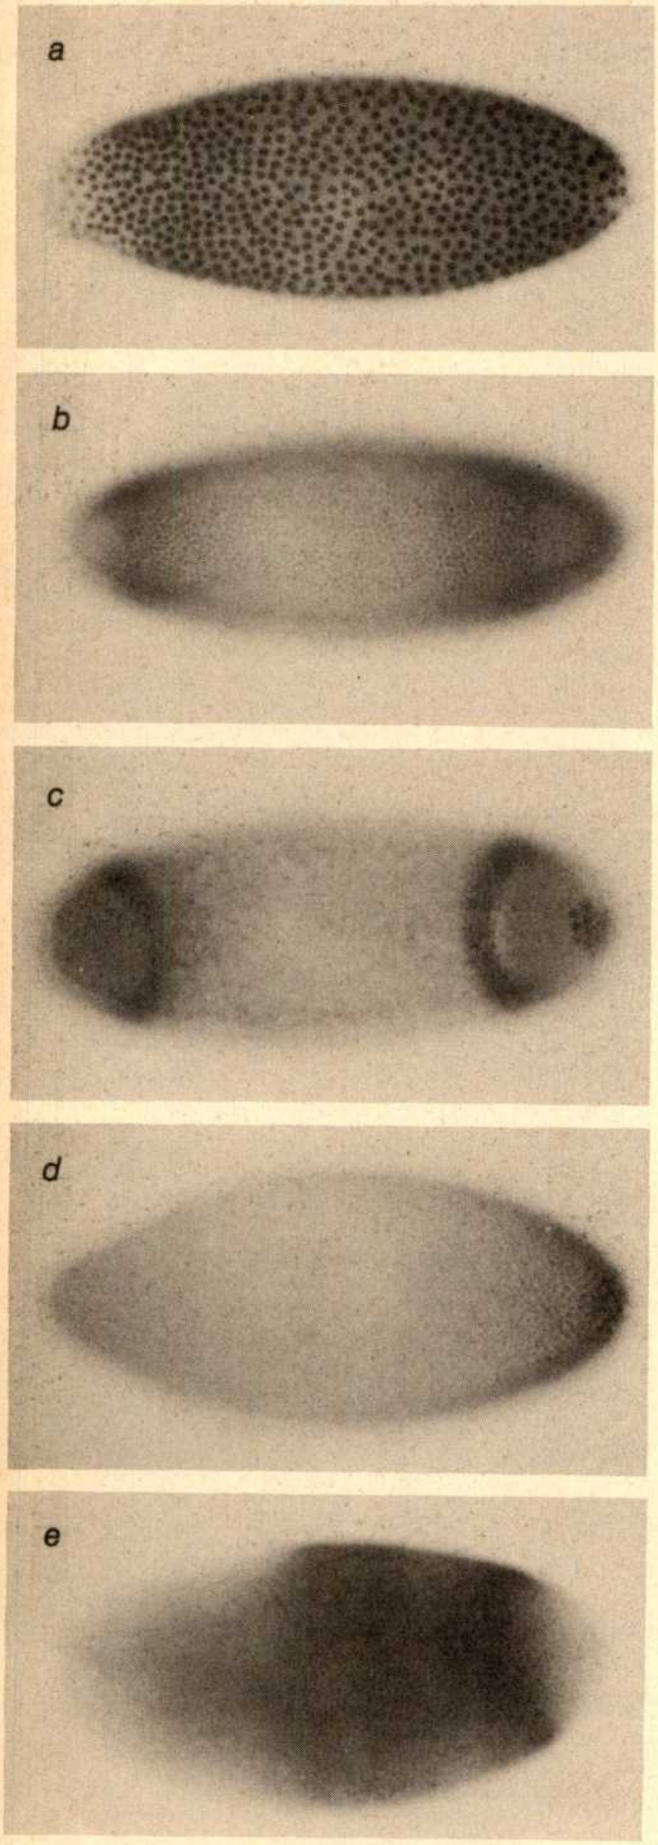


Fig. 5 Distribution of *cad* protein in *BicD* and *cad*$^{-}$ mutants. All embryos are oriented with anterior to the left and the plane of focus at the periphery of the egg. *a*, Stage 12 *BicD* embryo; *cad* protein is most abundant near the posterior pole, declines slightly towards the middle of the embryo and remains at a constant high level into the anterior region. The light staining at the anterior tip is commonly observed. Some variation in the overall pattern is seen in a population of embryos, as expected from the varying segmental phenotypes seen in populations of mutant embryos. *b*, Mid-stage 14 *BicD* embryo. Expression in the posterior ring, including the refinement of the initially broad region of staining, occurs roughly as normal, except that the ring forms at both ends. The pole cell nuclei (which are not in this plane of focus, but see *c*) stain intensely, as normal; there are no pole cells (or equivalent staining) at the anterior pole. *c*, Late stage 14 *BicD* embryo (dorsal aspect). Posterior and anterior rings are fully formed, both 3-4 nuclei wide. The width of the anterior ring can vary considerably, sometimes forming a stripe 10 or more cells wide. *d*, Mid-stage 14 *cad*$^{-}$ embryo derived from a *cad*$^{-}$/+ oocyte. The last traces of the gradient of *cad* protein can be seen near the labelled pole cell nuclei (see Fig. 2*g* for a wild type embryo at a comparable stage). *e*, Early-mid stage 14 embryo derived from a *cad*^{2} oocyte fertilized by wild type sperm (dorsal aspect). *cad* protein expression is similar to a comparably staged wild type embryo (Fig. 2*f*) except that no staining is observed in the pole cells. **Methods.** Antibody staining was as described (Fig. 2, legend), except for *e*; in this case, a strepavidin-alkaline phosphatase conjugate was used in place of the strepavidin-horseradish peroxidase conjugate, and the histochemical stain generated with the *black* kit (Vector Labs). *BicD* embryos were obtained from mothers transheterozygous for two different *BicD* alleles, *BicD*$^{71.34}$ and *BicD*$^{\mathrm{IIIF.48}}$ (ref. 15). Embryos that were *cad*$^{-}$ were obtained as $\frac{1}{4}$ of the progeny of a cross between mothers heterozygous for *Df(2L)TW2* and fathers heterozygous for *Df(2L)TW1*; both deficiencies delete the *cad* gene[45]. Similar results were obtained using embryos from selfcrosses of balanced *cad*$^{2-4}$ mutants. The *cad*^{2} eggs fertilized by wild type sperm were obtained by fertilizing females carrying germ line clones of the *cad*^{2} mutation with *cad*$^{+}$ males (see Fig. 4).

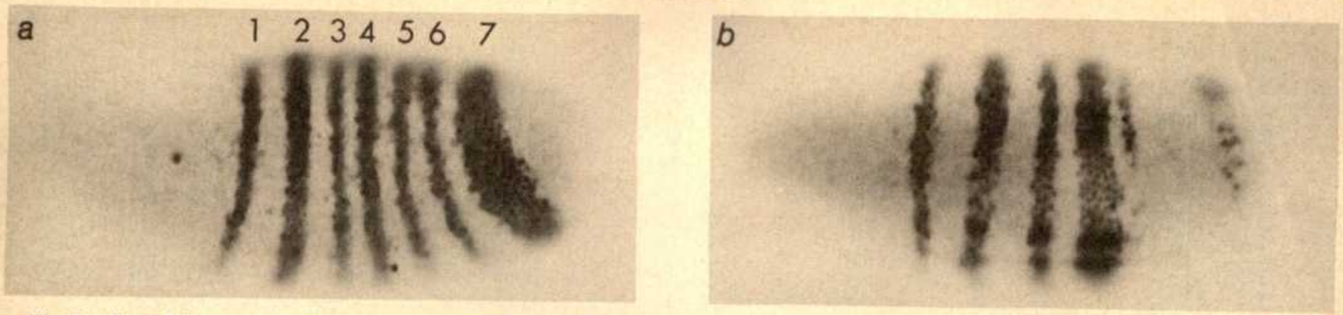

Fig. 6 Altered *ftz* protein expression in paternally rescued and cad^- mutant embryos; $cad^2/+$ (*a*) and cad^2/cad^3 (*b*) embryos derived from homozygous cad^2 oocytes, stained for *ftz* protein expression at the onset of gastrulation (lateral aspect, anterior to the left, dorsal at the top). Wild type embryos at this stage normally express six stripes of *ftz* protein of equal width followed by a broader seventh stripe. In paternally rescued $cad^-/+$ embryos (*a*), stripes 2 and 4 are slightly wider, and stripes 3, 5 and 6 are slightly narrower than in wild type. This tendancy is dramatically accentuated in cad^- embryos (*b*), leading to the loss of stripe 6 and severe reduction of stripes 5 and 7. Immunohistochemical staining as in Fig. 4*e*, except that the NBT/BCIP detection system (BRL) was used instead of the Vector Labs *black* kit.

Although uniformly high levels of *cad* RNA are found throughout the early embryo[34,35], we detect *cad* protein only after the fourth or fifth nuclear division. Soon thereafter, as the *cad* protein gradient forms, the distribution of *cad* RNA also becomes graded. This correlation suggests that a single process is responsible for localizing both the mRNA and protein. Because graded *cad* protein expression can be generated in unfertilized eggs as well as in cad^- embryos derived from heterozygous mothers, this process must depend on post-ranscriptional events, rather than on graded zygotic transcription.

In principle, formation of the *cad* protein gradient might reflect a passive response to changes in the distribution of the RNA (for example, mobilization of the transcripts, or local degradation by a specific, spatially restricted nuclease). Alternatively, both the RNA and protein gradients might be controlled at the translational level. One example of how this could occur is through differential initiation of translation along the anteroposterior body axis. Assuming that mRNA associated with ribosomes is shielded from nonspecific nucleases[60,61], efficiently initiated translation near the posterior pole would produce a high level of *cad* protein and at the same time stabilize the RNA, while infrequently translated *cad* RNA at the anterior pole would be prone to degradation. Analysis of the *cad* gene (P.M.M., unpublished data) provides suggestive evidence that supports a translational control model, as the various maternal and zygotic transcripts include sets of in-frame start and stop codons upstream from the probable initiator AUG codon; similar elements clearly act in translational control of the yeast GCN4 mRNA[62,63]. Polar determinants, such as those posited by Sander[2] and others[9,17,18], might regulate translation of *cad* mRNA either directly, or indirectly through their effects on other control molecules.

We thank Barry Ganetzky, Trudi Schupbach, Janos Szabad, Eric Wieschaus, and Ted Wright for fly stocks, Seymour Benzer for the monoclonal antibody 8C5, Sean Carroll and Matthew Scott for the *ftz* antibody, Sean Carroll, George Deegan, Tad Goto, and Ariel Ruiz i Altaba for advice or assistance in preparation of antibodies, Anne Ephrussi, Janice Fischer, Peter Lawrence, Christianne Nüsslein-Volhard and Robin Wharton for critical comments on the manuscript, and Tom Maniatis for advice and support. This work was supported by the U.S. National Institute of Health (Program Project Grant 1PO1GM29301 to Tom Maniatis), the Howard Hughes Medical Institute, and the Damon Runyon-Walter Winchell Cancer Fund (Postdoctoral fellowship DRG-768 to P.M.M.).

Infrared variability of the BL lacertae object OJ287 since its outburst in 1983

W. K. Gear, E. I. Robson & L. M. J. Brown

School of Physics and Astronomy, Lancashire Polytechnic,
Preston PR1 2TQ, UK

In early 1983, OJ287 was seen to undergo an outburst in its optical and infrared emission[1]. Since then optical monitoring studies[2–4] have shown a general decline in the source brightness, with considerable fluctuations. We have monitored the near-infrared emission since the outburst. The fluxes have fluctuated considerably, with the lowest recordings being an order of magnitude less than those measured during the outburst. We have found an excellent correlation between infrared flux and spectral index; as the source gets fainter the spectrum gets steeper, and vice versa. We interpret this in terms of outbursts being due to injection or reacceleration of electrons with a constant energy index which subsequently steepens as the electrons are affected by radiation losses.

We began observing OJ287 in February 1983 as part of a larger programme studying the infrared to millimetre variability properties of a sample of Blazars[5,6]. Observations have been made at J (1.25 μm), H (1.65 μm), K (2.20 μm) and L (3.45 μm) on 16 different nights over the period February 1983 to April 1986. All data were obtained from the United Kingdom Infrared Telescope (UKIRT), using common-user InSb photometers. Calibration was performed against stars from the observatory standards list.

The results of the observations and calibration procedure are shown in Table 1. In Table 2, we also list the infrared spectral indices, obtained by a least-squares fit method, for the 14 of these occasions on which we had complete JHKL coverage. We also checked each spectrum for departures from a power law. Given the rather small wavelength range of our data, and taking into account the uncertainties, we found no significant departure from a single power law at any epoch. Figure 1 plots the variability of the infrared emission over the period 1983-86, where to avoid overcrowding, we have averaged together spectra taken over a period of <1 week. Note that none of the spectra in Fig. 1 has been displaced; the different fluxes represent genuine variability. The extent of variability shown in Fig. 1 is such that to be sure of defining the overall continuum of OJ287, one would need to obtain the whole spectrum over no more than a single night, and preferably an even shorter time than this.

Because of the extreme variability of OJ287 we cannot claim to have fully sampled its temporal behaviour; however we can search for overall patterns of behaviour, which are evidence for a single origin for the emission over this wavelength range, and can lead to insights into the physical mechanism producing the variability. Even from Fig. 1 it can be seen that there is a correlation between flux and spectral index. To clarify this, Fig. 2 shows the JHKL spectral indices plotted against the log of the J-band flux. For these 14 data, performing a linear regression taking into account the uncertainty in both the flux and spectral index, we find a correlation coefficient of 0.84, representing >99% certainty of correlation. The correlation is in the sense that as the flux decreases the spectrum steepens. Conversely, as the flux increases, the spectrum flattens.

Also plotted in Fig. 2, are data from ref. 1, taken at the peak of the 1983 outburst, and refs 7, 8, taken in January to April 1983. Combining these with the present data, we find an even better correlation coefficient of 0.91. This well-defined correlation confirms the trend found for a sample of Blazars including OJ287, but with less data[6].

The power-law infrared continuum, extreme variability and high polarization[1] observed in OJ287 indicate a synchrotron origin of the infrared emission. We can explain the behaviour observed in terms of a recurrent injection or reacceleration

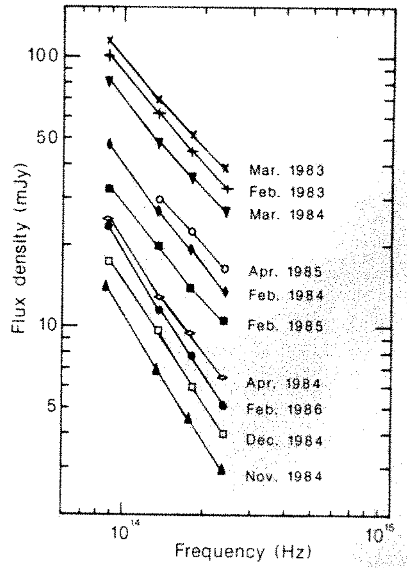

Fig. 1 The infrared spectrum of OJ287 at nine epochs over the period 1983-86. Note that none of the spectra has been displaced.

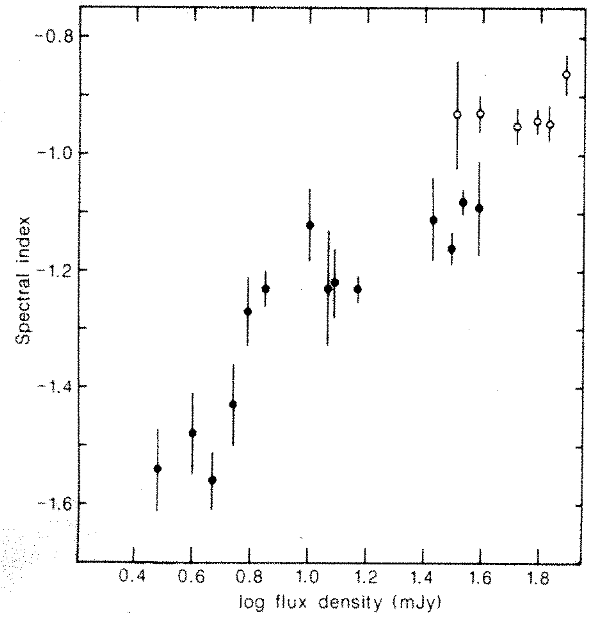

Fig. 2 A plot of infrared spectral index versus the log of the J-band flux showing a very good correlation; as the source gets fainter, the spectrum gets steeper, and vice versa. ●, JHKL spectra indices; ○, data from refs 1, 7, 8 taken at the peak of the 1983 outburst.

process. If the acceleration process produces an electron energy index of ~ -2.7 then an increase in the injection of electrons, or reacceleration of those already present, will result in an increase in emission with a spectral index ~ -0.85, such as was observed during the outburst in 1983 (ref. 1). These electrons will rapidly lose energy radiatively, however, (the results from ref. 6 suggest a magnetic field ~ 1 G in Blazars, corresponding to a lifetime measured in days for electrons radiating at $1\,\mu$m). The effective energy index will then steepen as the higher energy electrons are affected first and the observed spectrum will also steepen as it decays. In support of this conclusion we also note that there is some suggestion of a flattening in the correlation between the spectral index α_{JHKL} and $\log(S_J)$ (the log of the J-band flux) at high flux levels; this is to be expected because at high fluxes we are observing the native electron spectrum, unaffected by energy losses; the observed spectrum cannot become flatter than this.

Hanson and Coe[9] have found a similar correlation for the ultraviolet emission from OJ287 over the period 1983–84. Their ultraviolet spectral indices were generally steeper than those we see in the infrared (except when the infrared flux is very low, when the spectral index steepens to a value comparable with that seen in the ultraviolet). This implies that the ultraviolet spectrum is almost always steepened by energy losses, whereas in the infrared the true injected spectrum can sometimes be observed. We also note that from their optical UBVRI monitoring data in 1983, Moles *et al.*[4] find that the correlation between flux level and spectral index improves as one goes from the infrared into the optical region. This is probably an artefact of the spectral steepening over that wavelength range; the relative variations are larger at shorter wavelengths, due to shorter electron lifetimes, so for a limited data set the correlation will therefore show up more clearly.

The facts that the periods of increased flux after 1983 never reach the values of that outburst and that the spectral index never again reached the value of −0.85, suggest that subsequent events were not as powerful as that which caused the 1983 outburst. Continued infrared monitoring of OJ287 is essential to fully understand the emission from this extremely variable object. In particular, a long campaign of night-to-night monitoring would reveal whether this correlation is maintained on all timescales, or whether the source can take up some additional state. It would be particularly interesting to monitor OJ287 during a very low phase to discover if there was an underlying less variable component such as we have recently discovered[10] in 3C273.

OJ287 is an ideal source for this type of study, being highly variable, relatively bright and a Bl lac object so that one can directly observe the properties of the non-thermal emission over the whole spectrum. However, we note that after very careful removal of the recombination emission, Barr *et al.*[11] found a very similar correlation in the ultraviolet continuum emission from the Seyfert galaxy NGC3783. It is possible that the non-thermal emission from all active nuclei arises by a similar process, but that in many classes of object the behaviour is masked by relatively strong thermal and recombination emission.

We thank the UKIRT staff for their continued assistance with observations, particularly those obtained in service mode. W.K.G. and L.M.J.B. acknowledge financial support from SERC. UKIRT is operated by the Royal Observatory, Edinburgh, on behalf on SERC.

A new low-dimensional metal, $Cs[Pd(S_2C_2(CN)_2)_2]\cdot 0.5\,H_2O$

I. D. Parker*, R. H. Friend*, P. I. Clemenson† & A. E. Underhill†

* Cavendish Laboratory, Madingley Road, Cambridge CB3 0HE, UK

The discovery of a low-temperature superconducting state in organic compounds of the type $(TMTSF)_2ClO_4$ ($T_c = 1.2$ K) and $(BEDT\text{–}TTF)_2AuI_2$ ($T_c = 4$ K) (where TMTSF is tetramethyltetraselenafulvalene, BEDT–TTF is bis(ethylenedithiolo)tetrathiafalvalene and T_c is the superconducting transition temperature) has stimulated the search for new materials that may show higher values of T_c (refs 1–3). The general problem encountered in molecular charge-transfer salts of this type, which have conduction bands formed by intermolecular overlap of π-electron systems, is that conduction is usually quasi-one-dimensional, with good conduction along the stacking direction. Metals with this one-dimensional character are unstable, and undergo a Peierls transition[4] to a semiconducting state at low temperatures. The relatively few exceptions (mentioned above), which remain metallic down to low temperatures, are considered to do so because they show stronger interstack interactions. We report here a new material with inherently two-dimensional interactions between the molecular π-electron systems and which we are able to stabilize as a metal down to low temperatures (1.4 K) under hydrostatic pressure (12 kbar).

Molecular metals based on square coplanar metal complexes of the KCP ($K_2[Pt(CN)_4]Br_{0.30}\cdot 3H_2O$) type have been known for the past 15 years[5]. More recently the range of compounds with metallic properties has been extended to metal-dithiolene

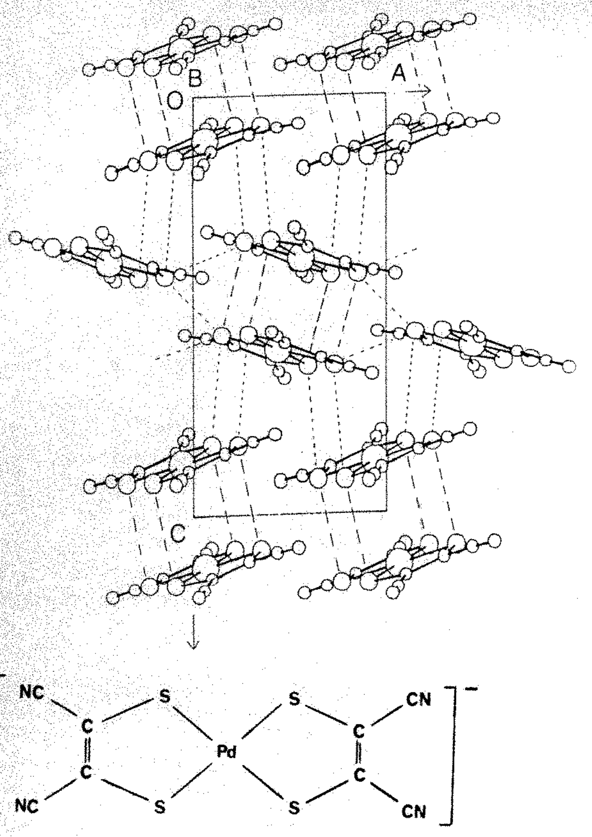

Fig. 1 *b*-Axis projection of the crystal structure of Cs[Pd($S_2C_2(CN)_2)_2$]·0.5 H_2O. The short S-S contacts are shown by dashed lines. Also shown is the molecular structure of [Pd($S_2C_2(CN)_2)_2$]$^-$.

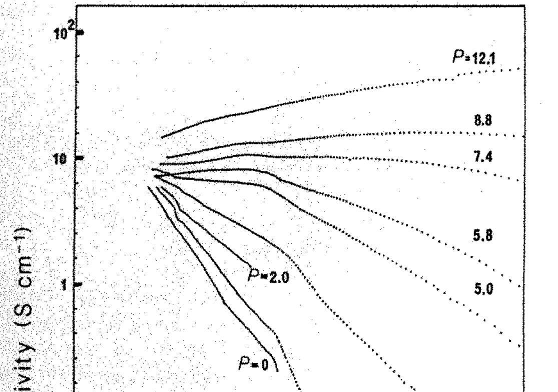

Fig. 2 Conductivity plotted against reciprocal temperature at several pressures (in kbar) for Cs[Pd($S_2C_2(CN)_2)_2$]·0.5 H_2O.

complexes[6]. Figure 1 shows molecular structure of the system of interest here. These are of particular interest because the intermolecular delocalization involves the π-electron systems on the ligands rather than the metal d orbitals (as in KCP). Up to now, all those molecular metals based on metal complexes have been of non-integral oxidation state; the chemical non-stoichiometry of the compound results in partial charge on the complex anion, the conduction band is consequently only partly filled, and metallic behaviour results. For a stoichiometric complex with a single (integral) charge on the anion, the Peierls distortion is of the form of a simple stack dimerization. This distortion is usually very strong and metallic properties are not expected in such materials, even at room temperature. There are several examples of such semiconducting behaviour[7]. Nevertheless, in Cs[Pd($S_2C_2(CN)_2)_2$]·0.5 H_2O we have discovered the first example of an integral-oxidation-state complex with metallic properties.

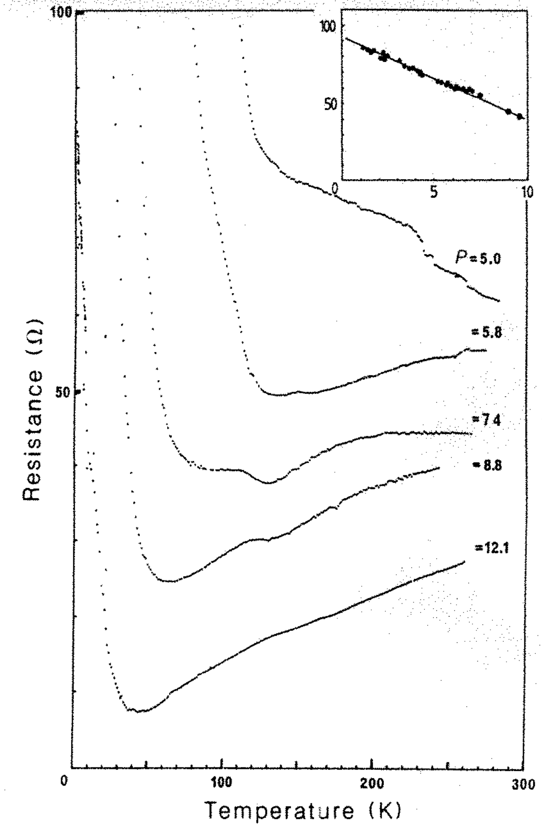

Fig. 3 Resistance plotted against temperature for Cs[Pd($S_2C_2(CN)_2)_2$]·0.5 H_2O. Inset shows the variation of resistance in the region 0–10 K.

Black plate-like crystals of Cs[Pd($S_2C_2(CN)_2)_2$]·0.5 H_2O were prepared by electrocrystallization from an aqueous solution of the dianion salt. Chemical analysis showed the compound to be stoichiometric. The crystal structure has been determined[7]; the structure consists of sheets of the [Pd($S_2C_2(CN)_2)_2$]$^-$ anions separated by layers of Cs^+ and H_2O along the *b* direction. Figure 1 shows the projection of the [Pd($S_2C_2(CN)_2)_2$]$^-$ anions normal to the sheet, and reveals the two-dimensional character of the structure. The [Pd($S_2C_2(CN)_2)_2$]$^-$ anions form dimers in an eclipsed configuration with an intra-dimer distance of 3.329(5) Å, but these are arranged so that there are short S-S contacts between dimers, 3.807 Å along the *c* direction but only 3.576 Å along the *a* direction.

At ambient pressure this material has a room-temperature conductivity of about 5 S cm^{-1} but it is semiconducting at lower temperatures[7]. For measurements under pressure we used a Be-Cu high-pressure cell capable of operation at up to 12 kbar in the temperature range 1.4–300 K (ref. 8). Four terminal measurements of the *a* axis conductivity were made using gold paste contacts. The conductivity at room temperature rises rapidly with pressure, but the changes at lower temperatures are more dramatic, with a transition from semiconducting to metallic behaviour. Results are shown in Figs 2 and 3. Figure 2 plots conductivity against reciprocal temperature, and the

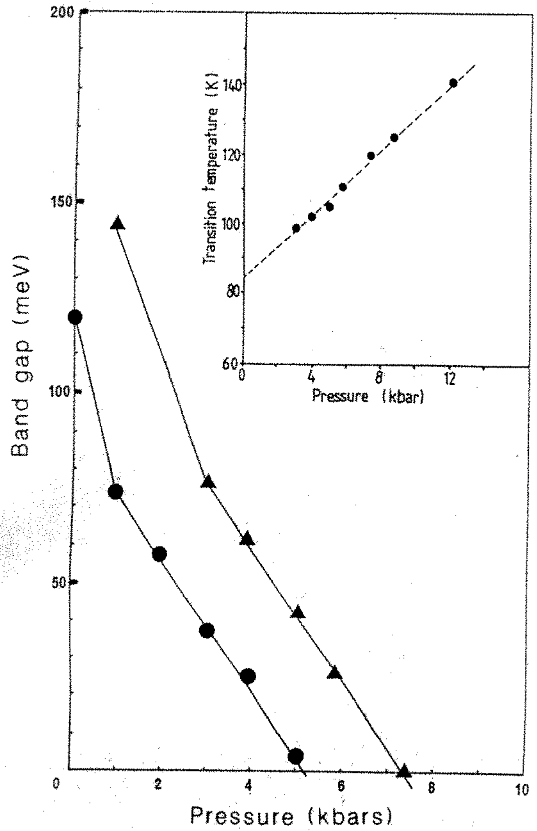

Fig. 4 Activation energies and transition temperature for the semiconducting phases of $Cs[Pd(S_2C_2(CN)_2)_2]\cdot 0.5\ H_2O$ as a function of pressure (band gap = 2 × activation energy). ●, Higher-temperature phase; ▲, lower-temperature phase.

(negative) straight-line slopes give the activation energies for conduction in the semiconducting regime. There is a monotonic decrease in activation energy to zero at about 7 kbar. Figure 3 plots resistance against temperature and shows the linear variation expected for simple metals over much of the temperature regime. At low temperatures the resistance shows an upturn; at 8.8 kbar and below this gives semiconducting behaviour. At the highest pressure investigated, 12.1 kbar, the resistance rise below 40 K is very weak, as shown more clearly in the inset to Fig. 3, and the conductivity at 1.4 K is still above 10 S cm^{-1}.

We have thus established that the conductivity can be kept at metallic levels under pressure but we need to understand why this is not so at ambient pressure. There are clues to this in the behaviour in the semiconducting regime, which is best seen in Fig. 2. There is considerable structure in the data shown, with at least two clearly defined slopes and a sharp break between them. Figure 4 shows the pressure dependence of the activation energies and of the temperature of the transition between them (chosen to be at the peak value of $\partial \ln(\text{conductivity})/\partial(1/T)$). The transitions between these phases are not of the Peierls type. For the Peierls transition there is a linear scaling between the size of the semiconducting gap and the temperature at which the transition occurs[9], whereas we see here that the transition temperature rises while the activation energies fall. We consider instead that the transitions involve some small molecular reorientations which set up appropriate superlattice potentials to 'accidentally' introduce energy gaps in the electron energy bands at the Fermi energy. We think that the effect of pressure may be to increase the intermolecular interactions to such an extent that although the structural transitions may still occur, their effect on the electron levels is diminished. Low-temperature structural measurements are required to follow this.

Organ pipe radiant modes of periodic micromachined silicon surfaces

Peter J. Hesketh*, Jay N. Zemel* & Benjamin Gebhart†

* Department of Electrical Engineering and † Department of Mechanical Engineering and Applied Mechanics, University of Pennsylvania, Philadelphia, Pennsylvania 19104-6390, USA

In recent studies on small pyroelectric thermal anemometers with roughened surfaces we showed that one of the most widely used heat transfer models[1,2] yielded calculated anemometer responses for flow and geometric behaviour that agreed functionally with observations, but were significantly smaller than the experimental data[3–5]. As the first stage in investigating the role of small structures in heat transfer, we initiated a study of emittance from deep gratings. Here we report measurements at 400 °C of infrared ($3\ \mu m \leqslant \lambda \leqslant 14\ \mu m$), normal, s- and p-polarized spectral emittances of 45 μm deep, near square-wave gratings of heavily phosphorus doped (110) silicon (P content ~5×10^{19} cm^{-3}). The grating surface repeat scales, Λ, were 10, 14, 18 and 22 μm, yielding a range of Λ/λ from 0.14 to 7.33. The s-polarization vector was parallel to the grating slots. Both s and p spectral emittances had pronounced resonant periodicities with a characteristic length of ~42 μm. A reasonable explanation for this behaviour is the presence of standing waves in the air slots perpendicular to the silicon surface similar to those in an organ pipe. While the resonant amplitude of the s polarization does not depend significantly on Λ it does for the p polarization. No explanation for the Λ dependence of the p polarization is known.

Although radiant emission from macroscopic black bodies and flat, smooth metallic surfaces is well understood[6,7], emission from deep, near square-wave gratings when Λ is comparable to or <λ is not. The theory of radiant emission from structures whose scale, S, is comparable to or <λ, has drawn considerable attention[8–18]. Measurements of semiconductors emissivity gave information on the optical properties of bulk dopants[19–21]. The effect of surface asperities on metal emissivity has been thoroughly studied[22–27]. Generally, the polarized emissivity of rough metallic surfaces depends on the r.m.s. value of surface asperities with the energy concentrated at small polar angles[24–28]. The work on both s- and p-polarized photo-acoustic spectrum from a silvered bigrating is the closest to our study, but the depth (H) used was still ≪Λ (ref. 29 and see ref. 30).

Our experiments employed (110) oriented silicon wafers on which square-wave gratings were etched to a common depth of ~45 μm using standard photolithography and a 40% (w/v) solution of KOH at 52 °C. After etching, the microconfigured wafers were spin-coated with a phosphorus based dopant and heated at 1,250 °C for 10 h. The peak phosphorus surface concentration is in the $0.4\text{–}0.6\times10^{20}$ cm^{-3} regime from sheet resistance measurements. This carrier concentration yields an effective skin depth of ≤4 μm, for λ > 5 μm. Auger measurements gave surface phosphorus concentrations of ~1×10^{20} cm^{-3}, in good agreement with the sheet resistance measurements. The heavily doped back surfaces of the silicon wafers were used as heater elements. Figure 1*a* shows the grating and the polarizations studied. Figure 1*b* shows a scanning electron micrograph of a

grating with $\Lambda=22\ \mu\text{m}$. Chips (1×1 cm) containing the microconfigured surface were mounted in a specially designed low-thermal-loss holder. More energy was required to reach operating temperatures for microconfigured surfaced samples compared to the smooth surfaces. A black-body source was constructed from a copper cylinder. The temperature of the source and the temperature difference between it and the sample were monitored throughout the measurement sequence. The 400 °C black-body source, controlled to better than 0.01 °C, was used as a reference for stabilizing the silicon sample temperature. Temperature differences between the silicon sample and the black body were <0.5 °C. Temperature fluctuations in the sample were typically <0.1 °C during a measurement. The emissivity measurement system is shown in Fig. 2. The signal-to-noise ratios of the infrared detector were ~100:1 or better at the higher temperatures. Data obtained at lower temperatures agreed well with these observations. The data were processed with a small data logging system based on a single board Z-80 computer.

The measurement procedure consisted of logging the polarized spectral intensity of the 400 °C black-body and silicon grating, both at normal incidence. This corresponded to a polar angle, $\theta=0°$, and an azimuthal angle, $\Phi=90°$. The polarized

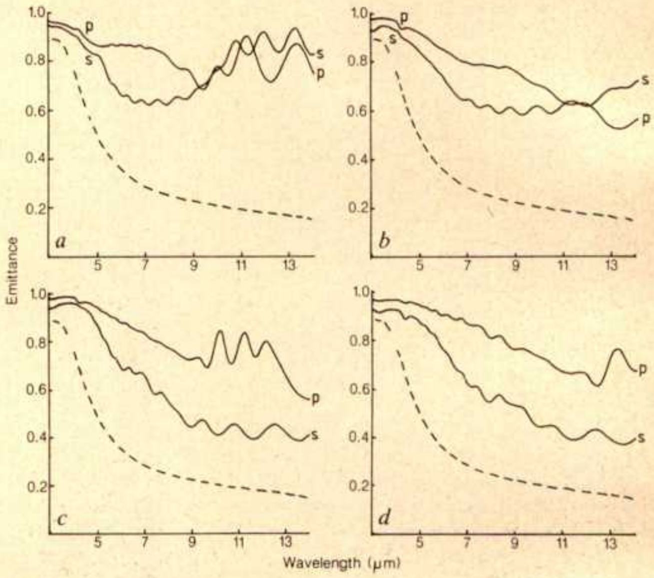

Fig. 3 Normal polarized, $T=400\,°\text{C}$, spectral emittance as a function of spectral wavelength for the p- and s-polarizations. For comparison, the smooth surface emittance is shown as the dashed line. All gratings had a depth $H=45\pm2\ \mu\text{m}$: *a*, $\Lambda=10\ \mu\text{m}$; $L=7.3\ \mu\text{m}$; *b*, $\Lambda=14\ \mu\text{m}$, $L=8.4\ \mu\text{m}$; *c*, $\Lambda=18\ \mu\text{m}$; $L=12.6\ \mu\text{m}$; *d*, $\Lambda=22\ \mu\text{m}$, $L=14\ \mu\text{m}$.

spectral emittance, $\varepsilon(^{\mathrm{s}}_{\mathrm{p}};\lambda;T=400\,°\mathrm{C})$ is defined as the ratio of these spectral intensities. For the above angles, the s-polarization vector is parallel and the p-polarization is perpendicular to the slots (Fig. 1*a*). Shifting Φ to 0° reverses the definitions of the s- and p-polarization vectors relative to the slots so they are perpendicular and parallel to the slots, respectively. The reproducibility of ε was 2–4% between runs. Pronounced periodic oscillations were found in both $\varepsilon(\mathrm{p};\lambda;400\,°\mathrm{C})$ and $\varepsilon(\mathrm{s};\lambda;400\,°\mathrm{C})$ from gratings with $\Lambda=10\ \mu\text{m}$, 14 μm, 18 μm, and 22 μm (Fig. 3). The value of ε for a smooth, heavily doped, silicon surface is shown in Fig. 3 as a dashed curve. Temperature had little influence on the magnitude of ε and essentially none on the period or amplitude of the observed oscillations.

The wavenumber, $K^{(i)}$, corresponding to maxima in the polarized spectral emittance ($K_{\mathrm{m}}^{(i)}=1/\lambda_{\mathrm{m}}^{(i)}$, $i=\mathrm{s},\mathrm{p}$) were plotted against an integral mode number, $m^{(i)}$ (for the appropriate polarization, $i=s,p$). The origin of the $K_m^{(i)}$ plot for the individual gratings was adjusted so that the data overlapped as shown in Fig. 4. Note that there is essentially no influence of Λ on the slope. We constructed a model in which the $K_{\mathrm{m}}^{(i)}$ are related to the $m^{(i)}$ by

$$K_{\mathrm{m}}^{(i)}=\begin{cases} m^{(i)}/2H \\ (2m^{(i)}+1)/4H \end{cases} \qquad (1)$$

where the upper relation applies to modes where the nodes

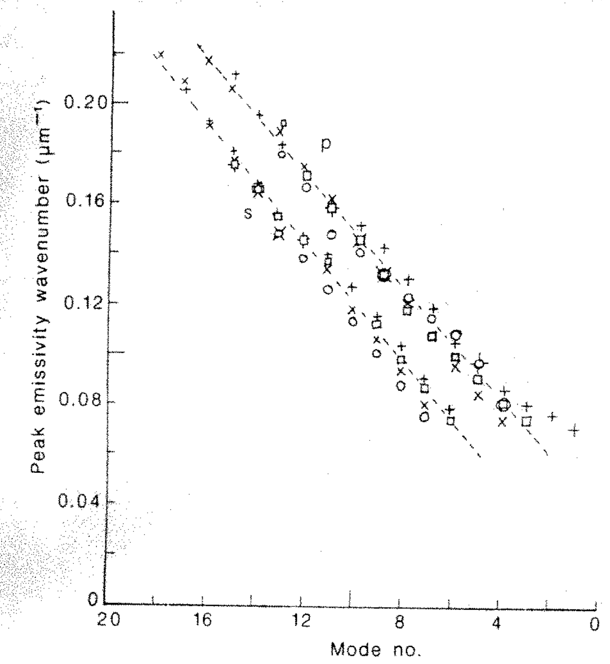

Fig. 4 Peak emittance wavenumber versus mode number; p- and s-polarizations; $H = 45 \pm 2$ µm; Λ, ○ = 10 µm; ⊙ = 14 µm; + = 18 µm; × = 22 µm.

occur at 0 and H and the second where one node occurs at 0 and the anti-node is at H. In both cases,

$$\Delta K_{\mathrm{m}}^{(i)} = \Delta m^{(i)}/2H \qquad (2)$$

From Fig. 4, $H = 42$ µm in striking agreement with the average depth of ~45 µm measured for the four different gratings. This is even more remarkable because Λ varies by a factor of >2. Whereas the slope of $K_{\mathrm{m}}^{(i)}(m^{(i)})$ is independent of Λ, inspection of the amplitudes of the emittance oscillation of Fig. 3 suggests that the p-polarized data oscillations are far more sensitive to Λ than are the s-polarized. We do not yet have any explanation for this difference.

The s-polarized emittance oscillations have no parallel in either experiment or theory. Work by Inagaki *et al.* suggests that periodic resonant absorptance occurs on a bigrating, but their data indicate that the magnitude of the absorptance is much smaller for the s-polarization than for the p-polarization[29]. Recent calculations show that substantial field enhancement arises in the slots of a deep cavity for the s-polarizations[14,18]. However, the far-field pattern associated with these s-polarized radiative modes is weak and almost identical to those from a smooth mirror of similar composition. In our structures, thermal energy populating the radiative (or absorptive) modes of the deep grating structure may be coupled out by asperities in the slot geometries. In any case, the peaks in the emittance are due to emission from 'organ pipe' or planckian type resonant modes in the slots of the grating.

We thank Judson Infrared for the HgCdTe infrared detector, Dr A. Ipri for supplying the photomasks; the EEMS Program of the NSF for partial support, D. Silversmith, Program Manager, under grant ECS-84-12241 (P.H., J.N.Z.); partial support from NSF grant CBT-84-18517 (B.G.); and Professors H. Baltes and A. Maradudin for useful discussions.

Evidence for a link between atmospheric thermonuclear detonations and nitric acid

G. Holdsworth

National Hydrology Research Institute and
Arctic Institute of North America, University of Calgary,
2500 University Drive N.W., Calgary, Alberta, Canada T2N 1N4

Suitably located glacier cores, obtained from high-altitude, low-temperature sites, can reveal detailed information about atmospheric air chemistry at sub-annual resolution[1]. Such data may provide input to climate-change models, the study of acid precipitation patterns and many other phenomena. Here I present data from an ice core which show that during the era of intense atmospheric thermonuclear weapons testing (ATWT) a significant part of the nitrate content in the snow was modulated by the intensity of the nuclear detonations. The fixation of nitrogen by nuclear fireballs leads to NO_x gases in the atmosphere[2] and ultimately to nitric acid in precipitation. At certain concentrations, these gases and the associated aerosols may perturb the climate[3,4].

In 1980 a series of snow and ice cores were retrieved from an altitude of 5340 m (approximately the 500 mbar or mid-troposphere level) on the upper plateau of Mt Logan (60° 36′ N; 140° 30′ W) in the Yukon Territory, Canada. The recorded mean annual snow temperature is −28.5 °C and the mean net annual accumulation rate is ~0.37 m water equivalent. The gross β-activity levels in the upper part of one of these cores were determined to a depth of almost 27 m, corresponding to about the year 1943 (ref. 1). These data were interpreted in terms of the known chronology of ATWTs[1,5].

Analyses for the major ions in the firn were performed at the Laboratoire de Glaciologie, CNRS, Grenoble, for a section of core between 10 and 21 m (AD 1967–1953)[6]. Inspection of the nitrate concentration data and the gross β-activity curve showed that these two data sets shared several major features: a prominent 1963 maximum preceded by a ~1960 (temporary moratorium) minimum and followed by another (post-1962 limited test ban treaty) minimum in ~1966. Analyses of the upper 10 m of core, with overlap on the lower section, were then carried out at the University of Calgary, using the same precautions exercised earlier[6,7]. For these purposes a parallel

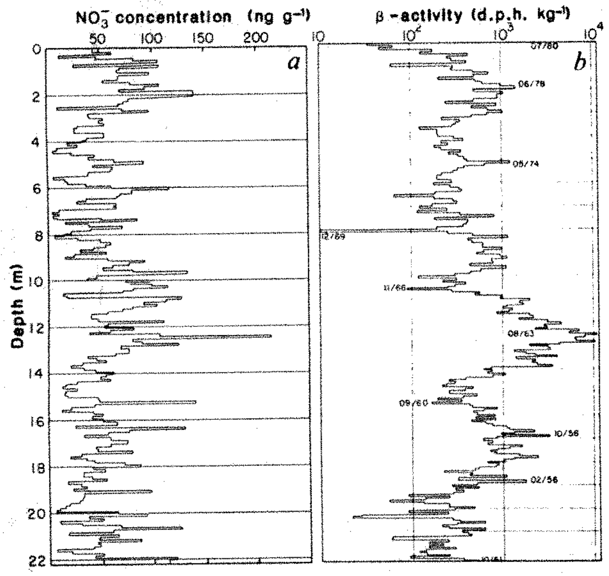

Fig. 1 *a*, Raw data for nitrate concentration and *b*, gross β-activity levels plotted against depth in the core. The top of the core corresponds to mid-1980 and the bottom to ~1952. Prominent peaks and troughs in *b* have dates assigned according to ref. 1.

core taken within 1 m of the earlier core[6] was analysed, thus providing a check on the consistency of results. At the 0.10 m cutting interval used, spikes in the nitrate and other anion data are quite common and cannot be associated with contamination. Contamination is further discussed in the section dealing with the origin of nitrates in the core. A comparison was then made between the upper 10 m of nitrate data and the gross β-activity curve (Fig. 1). This comparison revealed that, at least from 1973 to 1980, the People's Republic of China ATWTs were tending to modulate the NO_3^- levels.

Because the Chinese and the preceding Soviet ATWTs were done at locations with the same general latitude (±15°) as Mt Logan, and because the latter represents a relatively near-field site, it is not unexpected that the chemistry of the core should be influenced by these ATWT events. It has already been shown[8] that ATWT events produce copious quantities of nitric oxide (NO) (~10^{10} g Mt^{-1}). Although most of the detonations were made in the troposphere, large quantities of NO were injected, with other explosion products, into the stratosphere, where the residence time of the gases and aerosols could be up to several years[8].

A timescale for the core was established[1] to an accuracy of between ±0.25 yr and ±0.5 yr. The original data (typically 10 samples per year) were then converted into 6-monthly mean values to produce the time series of gross β-activity and $[NO_3^-]$ shown in Fig. 2. This particular time interval used for averaging represents the shortest unit that can be justifiably used while still preserving significant structure in the time series. Further smoothing was carried out for cross-correlation purposes. An attempt was made to reconstruct the gross β-activity values to their original values at the time the snow was deposited. This would allow a closer comparison to be made between gross β-activity and $[NO_3^-]$ with respect to amplitude information. The dashed blocks in Fig. 2*b* correspond to a simple radioactive decay correction based on the assumption that the dominant radionuclides present were ^{90}Sr and ^{137}Cs. This assumption is evidently not a good approximation for the most recent 8 yr of data[9], but reconstructions made using a sample-age-dependent effective half life[9] yield results at variance with the gross β-activity data[1] for air. Errors introduced by this adjustment of the data will not materially affect the major conclusions of this paper.

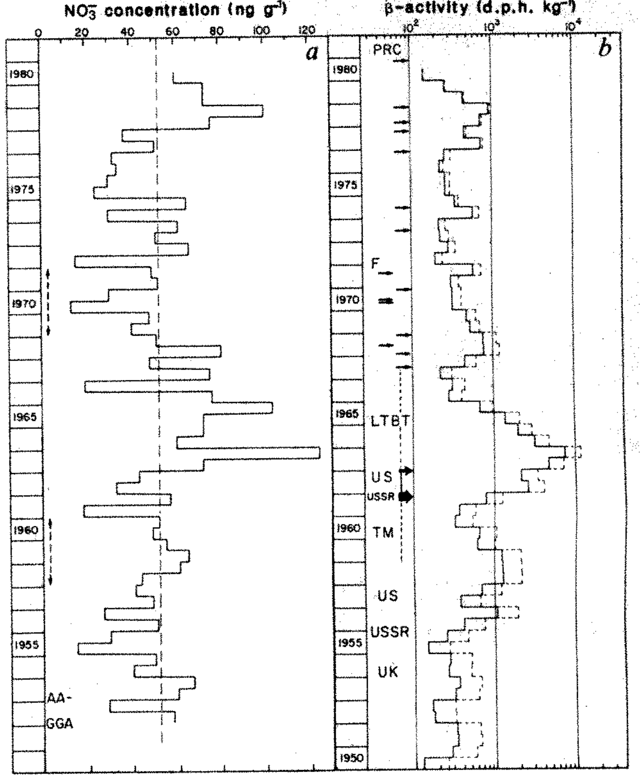

Fig. 2 Time-series plots of *a*, nitrate concentration, where broken arrows indicate position of auroral activity (AA) or global geomagnetic activity (GGA) maxima[20] and *b*, gross β-activity levels, where the arrows indicate the dates of prominent atmospheric thermonuclear weapons testing (PRC, People's Republic of China; F, France; US, United States; USSR, Union of the Soviet Socialist Republic; UK, United Kingdom; TM, Temporary Moratorium; LTBT, Limited Test Ban Treaty). The dashed blocks above the solid blocks indicates an approximate reconstruction of the original gross β-activity levels at the time of deposition.

Cross-spectral analyses were performed on the two time series. From the measured values of the gross β-activity, *A*, the value of the cross-correlation coefficient, *r*, between the two series is +0.42 at zero lag and +0.45 to +0.48 at 2-2.5 yr lag. From the decay-corrected gross β-activity values, A_0 the corresponding values of *r* are +0.41 and +0.44 to +0.47 respectively, all significant at the 95% level. For other lags the correlation is not significant. The coherence at zero lag was expected, as the two time series exhibit this feature visually. A clear explanation for the apparent correlation at 2-2.5 yr lag cannot be offered. It may represent a statistical artefact.

Several studies[10-13] concerned with the origin of nitrate in snow, firn and ice cores give twelve possible sources of this major trace ion, including atmospheric thermonuclear explosions. Local contamination of the core is not considered applicable here. Strict procedures and controls employed during sampling and analysis ensured that nitrate contamination was not significant. Measurements were made at two independent research institutions and a third commercial laboratory as a check by two different methods (ion chromatography and colorimetry). The core was independently sampled for gross β-activity, and as that curve resembles quite closely other published curves from different regions of the world[1,5], it is concluded that contamination cannot be significant. Finally, variations in nitrate in the core may also result from changes in accumulation rate[12], ablation, or meteorological parameters not associated with these quantities.

It is not possible to quantify each of the above sources in a detailed manner and it is furthermore evident that relative contributions from these sources vary geographically, both regionally[7,10-12] and with altitude[13,14]. It was shown[7] that no detectable trends in either $[SO_4^{2-}]$ or $[NO_3^-]$ exist in the Mt Logan snow from ~1880 to 1980, thus evidently eliminating anthropogenic input related to fuel combustion, as interpreted from ice cores from lower-altitude Greenland and the NE Canadian Arctic[15-17]. Therefore the most likely sources for significant nitrate input to Mt Logan snow in the specific time interval considered here are: (1) ionization in the upper atmosphere from various sources[10,11], (2) meteoroid fixation[10,11], (3) photochemical fixation[10,11,18], (4) volcanic emissions[7,19] and (5) atmospheric thermonuclear weapons testing[8]. The one mechanism for producing ionization in the upper atmosphere for which there is an established cyclicity (sunspot-auroral activity) does not appear to produce a signal in these data or in the Greenland data[12]. In Fig. 2*a* the broken arrows indicate periods of maximum auroral and geomagnetic activity[20]. No data are available for evaluating sources (2) and (3). In addition, the period AD 1952-80 was not particularly marked by major volcanic eruptions close enough to Mt Logan to cause a significant $[NO_3^-]$ pulse, unlike in 1912 for Novarupta[7]. Most of the relatively large eruptions that occurred in the north Pacific during this period took place on the Kamchatka Peninsula[19]. There is no consistent correlation between these events and the peaks in $[NO_3^-]$ except for Kliuchevskoi (1965, 66) which has a volcanic explosive index (VEI) of 3, whereas others during this period had VEI values of 4 and 5 (ref. 19). However, gaseous emissions are not necessarily related to VEI[21,22]. There were other volcanic events[19] that occurred during the 1964-66 interval that could have contributed cumulatively to the significant peak in $[NO_3^-]$ for AD 1965±0.5, which is particularly anomalous with respect to the ATWT history. Of course, any input of nitrate from these volcanic sources depends quite crucially on air-mass trajectories. A sulphate peak occurs with the nitrate peak for 1965 (ref. 6) so at least some volcanic input is likely.

The generation of NO from ATWT explosions has been put on a semi-quantitative basis[8], thus providing an opportunity for checking whether the core data are consistent with theoretical estimates. The 1963-65 'excess' nitrate is defined as that amount above the mean for 1952-80, or 52 ng g^{-1} (Fig. 2*a*). It will be assumed initially that the 1965-66 spike, which does not correlate with an enhanced gross β-activity level, is due to ATWTs: in 1965 and 1966 the People's Republic of China conducted small ATWTs. This assumption would imply different transport processes or routes for the two atmospheric species being considered. Next, the excess nitrate is converted into a load value by using the net annual snow accumulation data for these years. This calculation yields a total value of 4.45×10^4 µg m^{-2} of NO_3^-, or roughly 4.5×10^4 µg m^{-2} of HNO_3. If this load density is assumed to apply uniformly over the Northern Hemisphere (2.54×10^{14} m^2) then a total of about 11 Tg of HNO_3 is obtained. This is surely an upper limit, because if most of this HNO_3 is derived from ATWT events originating in the USSR, then the load density at the Mt Logan site must be much higher than the average for the Northern Hemisphere, as it is for the gross β-activity[1]. Because it was found that the gross β-activity at Mt Logan was about 32% higher than in Greenland[1], it is reasonably assumed that the Mt Logan nitrate flux from ATWTs is also correspondingly higher than in Greenland. If the Mt Logan nitrate flux derived from ATWTs is assumed to be twice the northern hemispheric average, then the total load for the stated period would be reduced to about 6 Tg. If, now, the excess nitrate during 1965 and up to 1966 is due to local volcanic emissions, then by trimming off the 1965-66 spike to the long-term mean level, a revised total computed load would be close to 5 Tg.

Assuming that a 1 megatonne bomb yield produces ~10^{10} g NO, equivalent to ~2×10^{10} g HNO_3, and that 340 megatonnes of cumulative yield occurred between October 1961 and December 1962 (ref. 8), then the total yield of HNO_3 for this period would be ~6 Tg. Another estimate[2] of cumulative bomb yield for this period is <340 Mt, so that a lower nitrate load is possible. From these rough calculations it may be seen that the excess nitrate for 1963-65, as derived from Fig. 2*a*, is of the right order for it to be accounted for by the known ATWT events that occurred during the preceding period.

In conclusion, the data presented here suggest that the ATWT events of more than two decades ago generated significant quantities of nitric oxide, the precursor gas for the nitric acid found in the snow on Mt Logan. The all-time peak pulse in gross β-activity coincides with the largest nitrate pulse for the period 1952-80. The observed excess nitrate, above the three decades mean for the 1963-65 period, can roughly be accounted for if the theoretical predictions for ATWT-produced NO are correct. These results, together with the observation that the gross β-activity curve is similar to other curves covering the same period, from different parts of both hemispheres[5], strongly suggest a common physical connection between nitrate and the radionuclides responsible for the β-activity in the snow, rather than just a connection through a common transport process. This latter mechanism would almost certainly explain the significant coherence between $[SO_4^{2-}]$ and $[NO_3^-]$ found particularly in the lower 10 m section of the core studied. For these two species $r=+0.49$ at zero lag, significant at the 95% level. Because this applies during the interval that includes the heaviest ATWT detonations, it would appear that the radioactive particles were playing a dominant role in acting as the nuclei for the aerosols that carried both the H_2SO_4 and HNO_3, in accordance with stratospheric aerosol theory[4]. A possible mechanism for injecting the stratospheric aerosols into the troposphere could be tropopause folding[23], a process that may be enhanced by lower-stratosphere overloading. Lastly, more direct evidence suggesting a connection between the 1976 People's Republic of China ATWT to a pulse of atmospheric nitrate in filtered air samples has been reported (W. A. Sedlacek, E. J. Mroz, A. L. Lazrus and B. W. Gandrud, in preparation).

I thank P. Upton and A. Williams, and others associated with the Arctic Institute of North America; the ice core drilling team who made the recovery of the core possible; R. Delmas and W. Sedlacek for helpful discussions; B. Gosling and B. Smith for the statistical processing of the data; and R. VanEverdingen and J. Winchester for significant improvements to the manuscript, a preliminary version of which was presented at the 1985 AGU fall meeting in San Francisco. This paper is published with the approval of the Director, National Hydrology Research Institute, Canada.

Weakening of rock salt by water during long-term creep

Janos L. Urai, Christopher J. Spiers, Hendrik J. Zwart & Gordon S. Lister*

Institute of Earth Sciences, University of Utrecht, Budapestlaan 4,
3508 TA Utrecht, The Netherlands

The rheological properties of rock salt are of fundamental importance in predicting the long-term evolution of salt-based radioactive waste repositories and strategic storage caverns, and in modelling the formation of salt diapirs and associated oil traps[1,2]. The short-term, high-stress rheology of rock salt is well known from laboratory experiments; however, extrapolation to appropriately low stresses fails to predict the rapid flow seen in certain natural structures. Furthermore, experiments have failed to reproduce the recrystallized microstructure of naturally deformed salt. Here we report experiments indicating that the above discrepancies can be explained by taking into account the influence of trace amounts of brine. Trace brine is always present in natural salt but sometimes escapes during experiments. Our tests on dry dilated salt show more or less conventional dislocation creep behaviour, but brine-bearing samples show marked weakening at low strain rates. This is associated with dynamic recrystallization and a change of deformation mechanism to solution transfer creep. Because natural rock salt always contains some brine, these results cast substantial doubt on the validity of presently accepted dislocation creep laws for predicting the long-term rheological behaviour of salt in nature.

Creep of rock salt has been the subject of extensive investigations over the past two decades[1]. Existing data[3,4] show good agreement for a wide range of rock salts, and satisfactorily describe short-term mine convergence[5]. Long-term rheological properties, however, are not accessible in the laboratory, and predictions are generally based on extrapolation. All previous experimental work indicates that 'dislocation creep' is the most important deformation mechanism in salt. This mechanism also seems common during natural deformation, as evidenced by preferred lattice orientations[1,6] and the presence of dislocation substructures[7]. However, many naturally deformed salts also show evidence of (dynamic) recrystallization by grain-boundary migration[8,9], a process rarely observed in experiments[6,10] and generally held to be impossible under natural conditions[1,11,12]. This discrepancy between the microstructure of naturally and experimentally deformed salt casts doubt on the applicability of laboratory flow data to natural deformation, as it suggests a change in microscale processes at low strain rates.

The flow rates of salt glaciers increase dramatically after a few centimetres of rainfall[13,14], to rates several orders of magnitude faster than suggested by experimental data, and the salt apparently undergoes extensive recrystallization. On this basis, it has been proposed that small amounts of brine can dramatically alter the deformation mechanisms and rheology of rock salt[13,15]. As all natural rock salts contain small amounts of brine (usually 0.1-1.0 wt.%)[16], the weakening effects of water operating in glacier salt should also be important in other salt deposits[13,14].

On theoretical grounds[8], even very small amounts of brine can be expected to influence salt creep. First, dynamic recrystallization can be strongly enhanced by thin brine films at grain boundaries[8,17]; secondly, such films can cause solution-transfer creep[8,17-20]; thirdly, water can diffuse into the sodium chloride lattice[21,22], possibly affecting dislocation dynamics. To investigate these possibilities, we conducted two series of experiments.

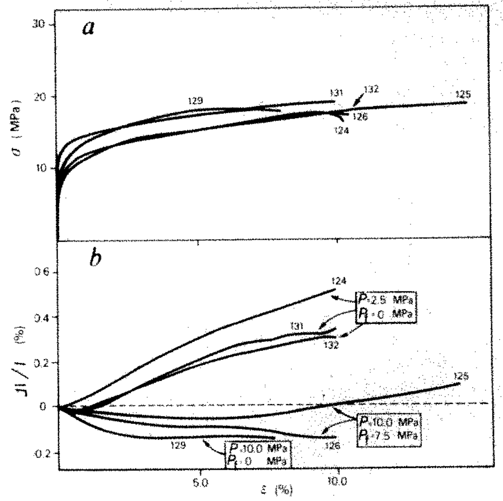

Fig. 1 *a*, Differential stress (σ) and *b*, volume change ($\Delta V/V$) plotted against strain (ε) for the pre-relaxation stage of the deformation experiments on natural (Asse) samples. $T = 150\,°\mathrm{C}$; $\dot{\varepsilon} = 3\times10^{-5}\,\mathrm{s}^{-1}$. The confining pressure (P) and pore fluid (brine) pressure (P_f) used in each test are indicated. Note that samples deformed at $P = 2.5$ MPa show substantial dilatancy (volume increase) compared with those deformed at $P = 10$ MPa.

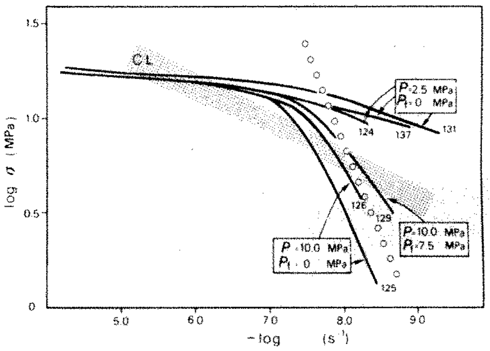

Fig. 2 Differential stress (σ) plotted against strain rate ($\dot{\varepsilon}$) (solid curves) for the stress relaxation stage of the experiments shown in Fig. 1. Note the dramatic weakening effect seen in samples deformed in non-dilatant conditions ($P = 10.0$ MPa), at strain rates of $<10^{-7}\,\mathrm{s}^{-1}$. This low-strain-rate behaviour can be described by a power-law creep equation, $\dot{\varepsilon} = A\sigma^n$, where the stress exponent (or stress sensitivity of strain rate, n) has a value of 1-2. Samples deformed in dilatant conditions ($P = 2.5$ MPa) are stronger than predicted by previously existing creep laws[1,3,4,25] (stippled area, Cl) but exhibit similar stress sensitivity (n values) at the lower strain rates. Note that the weakening behaviour observed in non-dilatant conditions ($P = 10.0$ MPa) agrees well with predictions based on the solution-precipitation creep model given in the text (equation (1)). This model was applied to the recrystallized samples using $d = 3$ mm, $a = 44$ (ref. 18) and $C = 8\times10^{-8}$ m (ref. 8). The diffusivity parameter B was estimated from published data[8].

In the first series, we used natural rock salt samples from the Asse Mine (West Germany). The material consists of a very pure (99%) halite rock, with a grain size of ~5 mm (Fig. 3*a*) and a dynamically recrystallized microsctructure[8,9]. The water content is ~0.05 wt%[23], up to half of which is present in fluid inclusions at grain boundaries (Fig. 3*b*, *i*). Right-cylindrical samples, 70 mm in diameter and 150 mm long, were machined from this material, and deformed at 150 °C at a constant strain rate of $\sim10^{-5}\,\mathrm{s}^{-1}$, followed by stress relaxation[8,24]. A dilatometric triaxial testing machine was used[8]. The pre-relaxation stress-strain behaviour was similar for all samples (Fig. 1), but clear differences were observed in dilatancy and stress relaxation (Figs 1, 2). Two types of behaviour can be distinguished: (1) Samples deformed at a confining pressure of

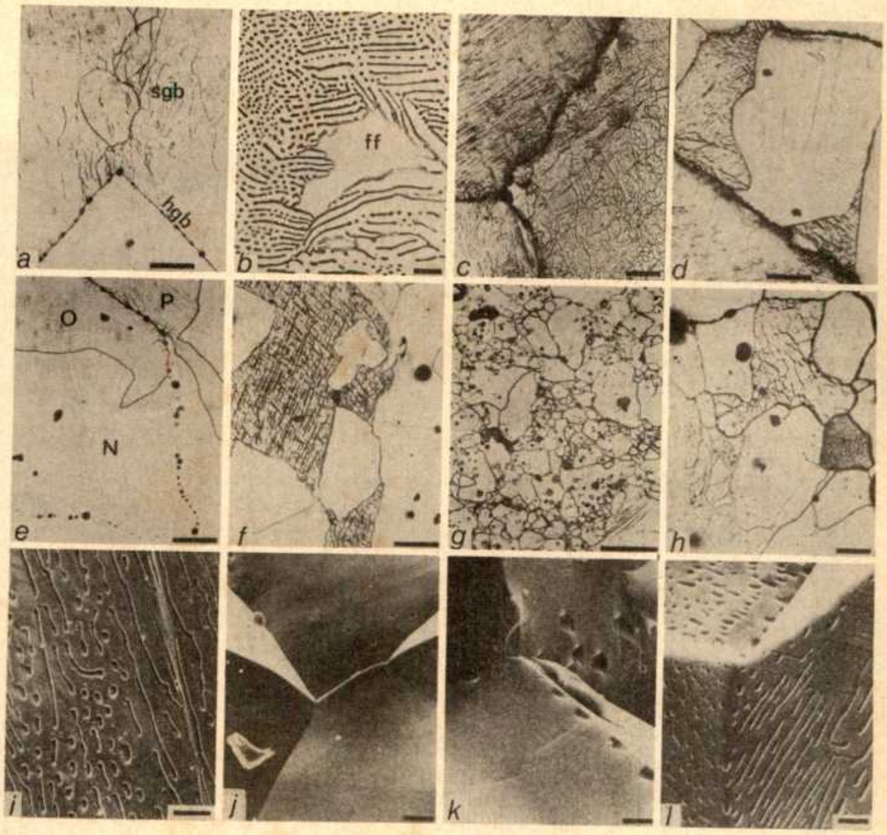

Fig. 3 *a*, Reflected-light micrograph of a polished and etched section of the natural starting material (from the Asse Mine) used in the present experiments. A grain containing subgrain boundaries (sgb) with a few degrees misorientation across them can be seen to be replaced by a newer grain, with fluid inclusions developed in the high-angle grain boundary (hgb) separating the two grains. Scale bar, 0.1 mm. *b*, Transmitted-light micrograph of the Asse salt shown in *a*, showing the typical structure of a high-angle boundary in plan view (see *i*). Note the array of fluid inclusions and fluid film segments (ff). These generally contain gas and/or brine. Scale bar, 0.1 mm. *c*, Reflection micrograph showing typical microsctructure of Asse salt samples deformed in dilatant conditions ($P = 2.5$ MPa). Note the densely developed slip-band structures, crude subgrains and dilated grain boundaries. Scale bar, 0.1 mm. *d*, Reflection micrograph illustrating the typical recrystallized microstructure of Asse samples deformed in non-dilatant conditions ($P = 10.0$ MPa). The micrograph shows a deformed grain with heavily developed dislocation substructure being replaced by a new grain with no visible substructure. The boundaries of new grains such as these can often be shown to contain thin brine films. Scale bar, 0.1 mm. *e*, Lobate new grain (N) consuming heavily deformed old grains (O, P) in a recrystallized Asse sample deformed in non-dilatant conditions. Note that gas-bearing inclusions in the boundary between grains O and P have been overgrown by the new grain N to form a 'ghost' grain boundary. Scale bar, 0.1 mm. *f*, Reflection micrograph showing dynamic recrystallization in a rock salt sample from Avery Island deformed to ~40% strain at $T = 70$ °C and $P = 20.4$ MPa, with differential stresses in the range 10.3–20.4 MPa. Again, note how new grains with relatively little substructure are growing at the expense of the old, heavily substructured grains. Scale bar, 0.1 mm (sample courtesy of Dr F. D. Hansen). *g*, Reflected-light micrograph of deformed sample of artificially prepared salt (grain size ≈80 μm; see Fig. 4 for mechanical data). Note the fine, equiaxial, largely recrystallized grain structure. The dark spots are pores emerging at the surface of the polished section. Scale bar, 0.1 mm. Neutron diffraction methods have shown that this sample has no significant crystallographic preferred orientation (H. G. Brokmeier, personal communication). *h*, Fine-grained, recrystallized microstructure in a sample from the salt glacier described in ref. 14. Compare this with *a*, *d*, *f* and *g*. Scale bar, 0.1 mm. *i*, Scanning electron micrograph of a mechanically parted grain boundary in a sample of the Asse salt used as starting material in our experiments on natural material (see *b*). Note the tendency of the grain-boundary fluid inclusions to develop negative crystal forms. Scale bar, 0.04 mm. *j*, Scanning electron micrograph of grain surface in a recrystallized Asse sample (see *d*), one month after the end of deformation in non-dilatant conditions. Note the smoothness of these surfaces. Such grain boundaries can be shown to contain brine by disrupting them *in situ* under the transmission optical microscope. The brine film thickness has been shown to be <100 nm by measuring triple-junction void diameters from scanning electron micrographs. Scale bar, 0.1 mm. *k*, *l*, Scanning electron micrographs of grain surfaces in a recrystallized Asse sample, tested in identical conditions to the sample shown in *j*, but observed 1 yr after the test ended. Note the clear changes in morphology. It is inferred that the observed arrays of inclusions formed by the breakdown of originally subcontinuous brine films, presumably by means of a solution–precipitation process driven by surface energy. This also offers an explanation for the grain-boundary inclusion arrays seen in the Asse starting material (*b*, *i*). Scale bars, 0.02 mm.

2.5 MPa (and without added brine) show marked dilatancy during the first stage of deformation. During relaxation at strain rates of $>10^{-7}\,\mathrm{s}^{-1}$, the differential stress is relatively insensitive to strain rate (Fig. 2). Microstructural analysis of the samples reveals densely developed deformation-band structures and crude subgrains (Fig. 3*c*). Grain boundaries are commonly dilated and fluid inclusions are disrupted (Fig. 3*c*). The overall behaviour agrees well with previous findings: work hardening is accompanied by some climb-controlled recovery[1,25].

(2) Samples deformed at 10 MPa confining pressure (with and without brine added) show little or no dilatancy during the first stage of the test. Furthermore, during stress relaxation there is a marked weakening below strain rates of $10^{-7}\,\mathrm{s}^{-1}$ (Fig. 2). In these samples, the grain size is reduced to about half that of the starting material. Optical microscopy shows deformed grains being replaced by new, recrystallized grains (Fig. 3*d*, *e*, *f*). The samples are ~70% recrystallized. New grain boundaries contain subcontinuous brine films (Fig. 3*i*–*l*) which are <100 nm thick.

The most likely explanation of the type (2) behaviour is as follows. During the first stage of the experiments, brine present in grain-boundary voids (Fig. 3*b*) is transformed into subcontinous brine films[26] which enhance grain boundary mobility. The grain boundaries then migrate, and the sample recrystallizes into a finer aggregate with lower dislocation density, and a network of brine-filled grain boundaries. The low values of the stress exponent n at strain rates below $10^{-7}\,\mathrm{s}^{-1}$ (Fig. 2) suggest that the dominant deformation mechanism changes from dislocation to solution-transfer creep[8,18,19]. This is supported by the finding (Fig. 2) that the observed weakening behaviour agrees well with the following theoretical model for diffusion-controlled solution-transfer creep[8]:

$$\dot{\varepsilon} = \frac{ABC\sigma}{kTd^3} \qquad (1)$$

where $\dot{\varepsilon}$ is the strain rate, σ is the applied stress, A is a constant, B is a temperature-dependent diffusivity term, C is a grain-boundary structure parameter, k is the Boltzmann constant, T is the absolute temperature and d is the grain size.

At low strain rates, the samples showing type (2) behaviour are much weaker than expected from previous data (see Fig. 2), the weakening effect becoming more pronounced towards lower strain rates. The absence of this weakening in type (1) samples

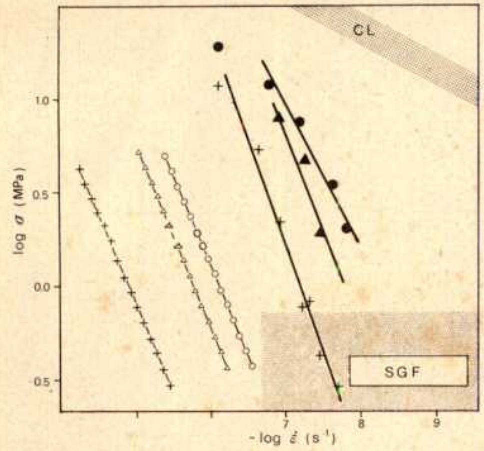

Fig. 4 Log σ plotted against log $\dot{\varepsilon}$ for three experiments on wet synthetic salt (solid lines), compared with the behaviour expected on the basis of previously existing creep laws[1,3,4,25] (stippled area, CL). The broken lines represent the behaviour predicted, for each of the three experiments reported, using the solution–precipitation creep model (eqn 1). Experiments: ●, $T = 20\,°C$; $d = 0.2$ mm; $P = 21$ MPa; $P_f = 3$ MPa; ▲, $T = 70\,°C$; $d = 0.2$ mm; $P = 21$ MPa; $P_f = 3$ MPa; +, $T = 20\,°C$; $d = 0.08$ mm; $P = 5.1$ MPa; $p_f = 0.1$ MPa. Model: ○, $T = 20\,°C$; $d = 0.2$ mm; △, $T = 70\,°C$; +, $T = 20\,°C$; $d = 0.08$ mm. Note the excellent agreement regarding stress sensitivity of strain rate ($n \approx 1$). The model was applied using $A = 44$ (ref. 18) and $c = 8 \times 10^{-8}$ m (ref. 8). The value of B was estimated from published data[8]. Finally, note that the experimental results reported in this diagram are almost directly relevant to the σ–$\dot{\varepsilon}$ conditions (stippled area, SGF) associated with the flow of wet salt glaciers in nature[13] ($d = 0.2$ mm).

(those samples deformed dry at pressure allowing dilatancy) can be explained by grain-boundary microcracking. This almost certainly leads to evaporation of the grain-boundary fluid.

In the second series of experiments we used artificial, fine-grained samples expected to exhibit accelerated solution-transfer creep effects (see equation (1)). These were prepared by dry compaction and annealing of fine-grained analytical-grade NaCl. The experiments were carried out in non-dilatant conditions using samples of 30 mm diameter and 60 mm length containing ~1% added brine[8]. A strain-rate stepping technique was used. The results indeed show the expected 'low n' behaviour (Fig. 4) and grain size dependence. Microstructural investigations show an equiaxial, recrystallized fabric, with little or no dislocation substructure (Fig. 3g), and no preferred lattice orientation. Grain boundaries were fluid-filled, with thicknesses of the same order as the recrystallized Asse samples. Most of the fluid was located in voids. Taken together, these observations provide evidence[20] that diffusive mass transfer was the main deformation mechanism, accompanied by grain-boundary sliding and migration. Comparison of the experimental data with the model of equation (1), applied using reasonable values of the parameters involved, gives good agreement for the stress exponent n (Fig. 4). Note also that the present experiments are almost directly relevant to the conditions found in salt glaciers (Figs 3h, 4), and show the weak behaviour reported in ref. 13.

Natural rock salt invariably contains small amounts of brine[16], part of which resides in grain-boundary fluid inclusions and films. Both sets of experiments reported here show that grain-boundary brine can have large effects on rheology and deformation mechanisms, by promoting dynamic recrystallization and solution transfer. In our opinion the weakening reported here has not been observed by previous workers on natural salt, either because the lowest strain rates reached were too high (Fig. 2), or because the water inherent in the samples was lost before testing. Note that most previous work has been performed in dilatant conditions. It is clear that in future long-term creep work, careful consideration should be given to recrystallization and grain-boundary fluid effects.

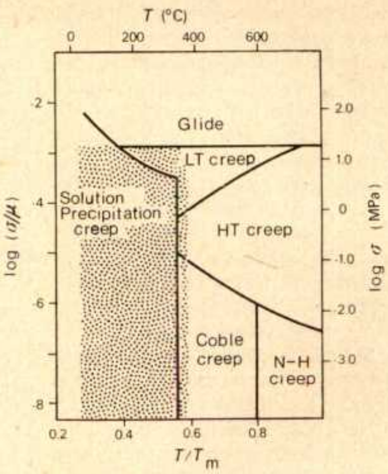

Fig. 5 Deformation mechanism map for halite (after ref. 28), modified to include solution-precipitation creep as described by the model given in the text (equation (1)). Values of the parameters A, B and C were chosen as for Figs 2 and 4. The map was constructed for a grain size of 1 mm and intergranular fluid pressure of 10 MPa. The extent of the solution-precipitation or solution-transfer creep field towards higher temperatures is assumed to be limited by the liquid–vapour phase transition. Stippling indicates the range of conditions relevant for halokinesis and radioactive waste repositories (the latter ranging up to only 200 °C). LT, low-temperature; HT, high-temperature; N–H, Nabarro–Herring.

Keeping in mind that our natural (Asse) starting material is relatively dry, weakening by water should occur in a wide range of salt rocks during natural deformation[17,27]. A rough extrapolation of our data to the grain sizes, tempertures, and differential stresses[7] expected during natural salt deformation suggests that brine-related effects should become important at strain rates of $\sim 10^{-10}\,s^{-1}$ (just below those accessible in the laboratory), and we propose that most natural salt deformation occurs in the transition zone between the dislocation-creep and solution-transfer fields. We further conclude that the extrapolation of previous flow laws to predict long-term behaviour is questionable, unless the effects reported here are also taken into account. Construction of a deformation mechanism map for salt (Fig. 5), incorporating solution–precipitation creep (equation (1)), shows that brine effects can be expected throughout a very wide range of natural conditions, including those relevant to radioactive waste repositories and storage caverns.

We thank H. Gies, C. J. Talbot and F. D. Hansen for supplying samples, C. J. Peach and J. L. Liezenberg for discussions and assistance with experimental work, J. N. Boland for help with electron microscopy, H.-G. Brokmeier for measuring preferred lattice orientations, and the workshop staff of the HPT laboratory at Utrecht for technical assistance. The work was performed under contract with the Netherlands Ministry of Economic Affairs and the Commission of the European Communities (contract WAS-153-80-7-N) in connection with their research programmes on radioactive waste management and storage.

Diagenesis of US Gulf Coast shales

K. Pye*, D. H. Krinsley† & J. H. Burton†

The burial diagenesis of mudstones is of major interest in petroleum geology[1-3]. Key questions which remain incompletely answered include the relative importance of temperature, time, changes in pore-water chemistry and organic maturation as driving mechanisms, and the relationship between diagenesis in mudstones and neighbouring sandstones[4-7]. We reconsider here the nature and timing of diagenesis in Gulf Coast Tertiary mudstones using data obtained by backscattered electron microscopy (BSEM) and energy-dispersive X-ray analysis (EDS) of cuttings from two Texas wells. Our observations confirm the mineralogical trends with depth reported by Hower *et al.*[1] and suggest new evidence concerning the timing and causes of the changes. The most important mineralogical changes occurred in the zone of organic matter decarboxylation (zone IV[8]). We show that the sequence of burial diagenetic events can be established quickly and reliably by BSEM examination of shale cuttings, and demonstrate the use of foram tests and their authigenic mineral infillings as indicators of diagenesis in soft, fine-grained shales.

The Tertiary mudstones and interbedded sandstones of the USA Gulf Coast represent one of the world's most intensively studied sedimentary sequences. Many fundamental concepts concerning the nature, timing and consequences of shale diagenesis were developed through work in this area[1,5,9-12]. Of particular interest has been the transformation of smectite in mixed-layer illite-smectite clays, involving an apparent increase in the proportion and ordering of illite layers with burial. It has been suggested that release of water during this transformation may be important in flushing out hydrocarbons from source rocks, in transporting ions for the formation and/or dissolution of cements in neighbouring reservoir sandstones, and in leading to over-pressuring and hydro-fracturing[3,9,13].

Several important questions have not been resolved in the classic work by Hower and his associates[1,11,14,15]. In particular, the sequence of mineralogical changes and the driving mechanism behind the diagenetic transformations were not positively identified. Decomposition of detrital potassium feldspar and mica during burial was suggested to provide the additional K^+ and Al^{3+} required for the transformation of smectite to illite[1], with release of Si^{4+}, Fe^{2+} and Mg^{2+} (reprecipitated as chlorite and quartz). It was suggested that substitution of Al^{3+} for Si^{4+} in the tetrahedral layers of the smectite was the principal factor allowing fixation of K^+ in the interlayer positions by increasing the layer negative charge. The reasons for the decomposition of K-feldspar and mica were not identified. Hower *et al.* also observed a gradual loss of calcite over the depth interval in which the clay transformations occurred (2,500-3,700 m), but no causal connection was suggested.

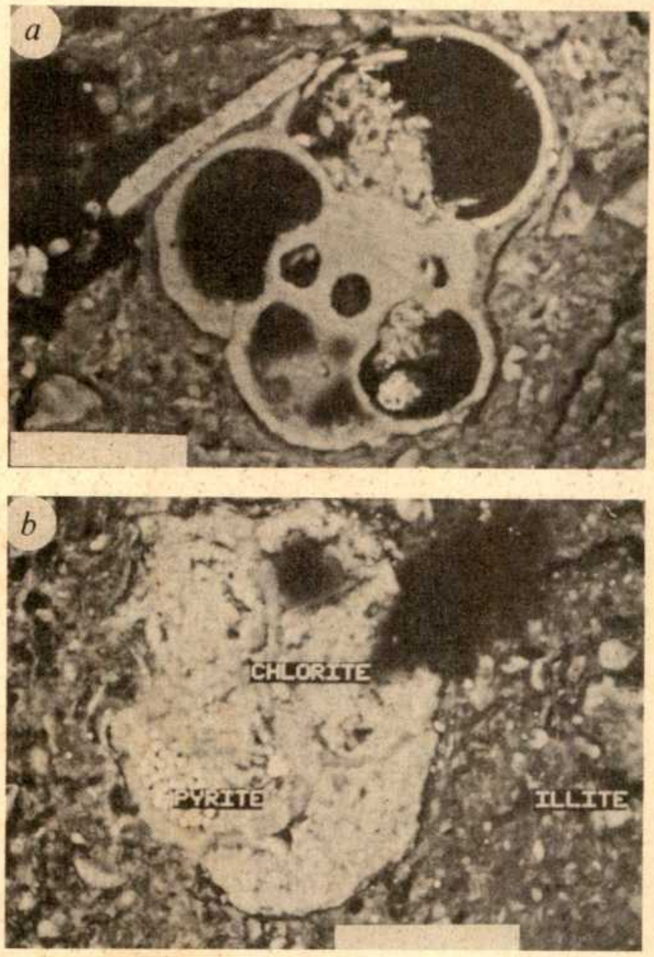

Fig. 1 BSEM micrographs of polished shale cuttings from C.W.R.U. Gulf Coast Well No. 6 showing: *a*, a calcite foram test partly infilled by authigenic chlorite (depth 2,680 m); and *b*, a foram completely infilled and replaced by chlorite (depth 3,415 m). The surrounding matrix consists mainly of illite-smectite and fine-grained quartz (scale bar, 50 μm).

De Segonzac[16] postulated that pressure is a major factor affecting clay transformations, but Perry and Hower[11] and Heling[17] concluded that temperature is more important. Other authors have stressed the role of pore-water chemistry, particularly K^+ availability[12,18]. Iron reduction[7,19] and organic matter maturation, leading to marked changes in shale porewater pH[5,6,20], have also been suggested to be important controls.

Previous Gulf Coast shale studies have relied mainly on 'bulk' methods of mineralogical and chemical analysis, particularly X-ray diffraction (XRD). No direct observations of textural relationships between different minerals with depth have been made, and diagenetic processes such as dissolution, precipitation and recrystalization have mainly been inferred from changes in relative mineral, elemental and isotopic abundance in different grain size fractions. We considered that useful information might be provided by examining polished shale cuttings using BSEM and EDS[21]. Cuttings from two south Texas wells were examined. The first sample suite spanned the depth interval 1,200-3,700 m in Case Western Reserve University Gulf Coast Well No. 6, previously studied by Hower *et al.*[1]. The second

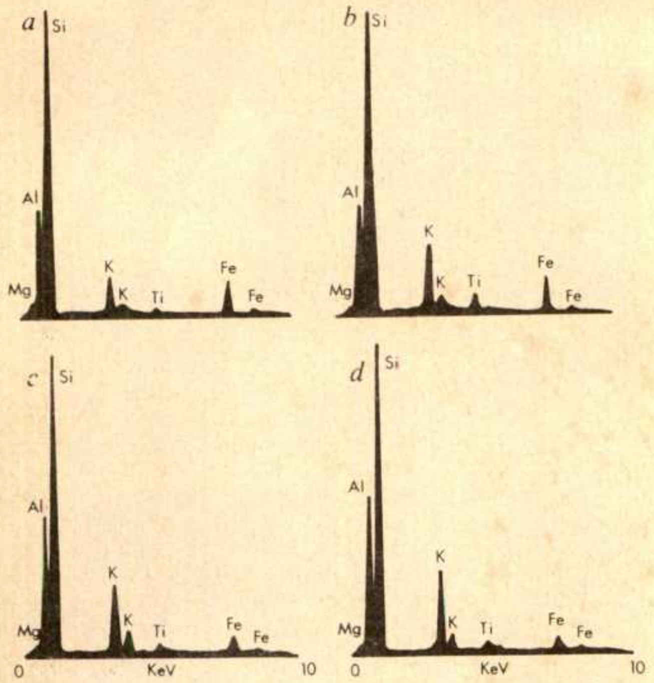

Fig. 2 Typical EDS spectra of illite–smectite aggregates showing observed changes in elemental peak heights with depth in Mobil Halls Bayou Wildcat No. 1. Samples are from depths of: *a*, 2,232 m; *b*, 3,650 m; *C*, 4,485 m; *d*, 5,530 m.

suite came from Mobil Halls Bayou Ranch No. 1 Wildcat, Galveston County. Both wells penetrate virtually the entire thickness of the Frio and Anahuac Formations which were deposited as a rapidly subsiding sediment wedge on the north side of the Gulf Coast Tertiary Basin[22,23]. The upper Frio consists of interbedded terrestrial and marginal marine sandstone and shale units underlain by >2,000 m of undercompacted slope and basinal mudstones. The Anahuac represents a transgressive, predominantly marine shale wedge which onlaps the Frio.

Shale cuttings from selected depth intervals were oriented and impregnated in epoxy for scanning electron microscope (SEM) examination transverse to the bedding. Due to their fine-grained, soft nature, many specimens were polished by hand to minimize surface damage. After carbon coating the specimens were examined in an ISI SEM equipped with a solid-state BSE detector and Kevex EDS analyser. Cuttings from each depth interval were also analysed by XRD.

Useful textural and chemical data were obtained from all but the finest-grained cuttings. Even in specimens composed largely of clay, clear indications of diagenetic reactions are provided by authigenic mineral aggregates within or replacing foram tests. In Gulf Coast Well No. 6, calcite foram tests are abundant above 2,750 m (Fig. 1*a*). The tests are partly filled by authigenic pyrite, kaolinite and chlorite, with some unoccupied pore space. Between 2,750 and 3,400 m the remaining voids are filled by authigenic chlorite and/or illite (Fig. 1*b*), while the tests themselves are dissolved. In some cases, the chambered structure of the tests is preserved by chlorite replacement, indicating that infilling of the intra-test voids occurred earlier than dissolution of the test walls. In the same depth interval, zoned authigenic carbonate rhombs, which were formed in the sulphate reduction and fermentation zones (zones II and III[8]), are also dissolved and replaced by iron-rich chlorite. These observations indicate a significant reduction in shale porewater *p*H in the temperature range 60–90 °C (see ref. 1 for down-hole temperature data).

Although the Frio mudstones contain many clay particles which cannot be resolved individually using BSEM, much of the illite–smectite clay (identified by XRD) occurs as aggregates up to 20 μm in size which may be compacted floccules. The aggregates are sufficiently mono-mineralic to allow semi-quantitative X-ray analysis of their chemical composition. The EDS spectra in Fig. 2 illustrate the general nature of the changes in composition of the illite–smectite aggregates with depth in the Mobil well. Similar trends were observed in C.W.R.U. Well No. 6. The illite–smectite above 2,500 m has a high Si/Al peak height ratio and a low K/Fe ratio, reflecting an abundance of smectite components. With increasing depth there is an increase in Al and K and a relative reduction in Si and Fe. This is in agreement with previous wet chemical data obtained from the fine-clay fractions[1] and corresponds with an increase in the proportion of illite components indicated by XRD[1]. In the Mobil well, the first change in composition of the illite–smectite indicated by EDS occurs at 3,620 m. At this depth, K abundance increases whereas Fe and Al abundance remains unchanged. With increasing depth there is a marked increase in Al and decrease in Fe while the K content remains almost constant. These observations suggest that the conversion of smectite to illite (if some form of solid-state transformation is occurring) is not dependent on tetrahedral substitution of Al^{3+} for Si^{4+}. However, it is possible that the creation of octahedral layer charge, due to the reduction of Fe^{3+}, during passage of the sediment through diagenetic zones II, III and IV, contributes to the fixation of interlayer K^{+}, as previously suggested by Eslinger *et al.*[24].

The infilling and replacement of some foram tests by illite indicates that this mineral is at least partly neoformed by direct precipitation from pore fluids.

K-feldspar was not present in large amounts in any of the cuttings studied, but bulk rock XRD analyses and SEM evidence indicated some reduction in abundance at slightly greater depth than carbonate dissolution, suggesting that carbonate may have acted as a temporary buffer which retarded dissolution of feldspar.

It has been suggested that thermal decarboxylation of kerogen in mudstones is the most probable mechanism whereby acid pore waters are generated at depth[20,25]. This may occur where production of CO$_2$ by decarboxylation exceeds iron reduction[7]. In the Gulf Coast, excess decarboxylation is favoured by a relatively high geothermal gradient and a rapid rate of burial. However, the Frio shales contain on average only 0.28% organic matter, and could not generate sufficient CO$_2$ to account for all of the secondary porosity observed in Frio sandstones plus the loss of carbonate originally present in the shales[5]. Aliphatic and other organic acid anions are also produced during decarboxylation[20,26], but a similar mass balance problem arises[5]. A further possibility is that, once initiated, the smectite–illite transformation generates residual acid, proton-donating water which may contribute to a lowering of *p*H[27,28].

From the textural and chemical data provided by BSE and EDS we conclude that the sequence of diagenetic changes was (1) reduction of *p*H due to excess decarboxylation during simultaneous iron reduction; (2) dissolution of carbonate; (3) dissolution of detrital feldspars and micas; (4) build-up of negative octahedral layer charge due to reduction of Fe^{3+} in mixed-layer clays; (4) fixation of interlayer K^{+} and substitution of Al^{3+} for tetrahedral Si^{4+}, the additional K and Al being derived from dissolved detrital silicates; (5) precipitation of neoformed illite and chlorite in pores, and partial replacement of kaolinite by chlorite. Some chlorite and/or berthierine[29] was precipitated within foram tests before the onset of carbonate dissolution in zone IV.

The pattern of shale diagenesis found in the Gulf Coast differs from that found in some other sedimentary basins, and it may be unwise to regard it as a general model. The Gulf Coast sediments initially contained a large iron-bearing smectite and mixed-layer clay component, were buried relatively rapidly, and experienced high thermal gradients. Consequently they bear an important imprint from diagenetic zone IV. In contrast, many British Jurassic mudstones initially contained little smectite or mixed-layer illite-smectite compared with kaolinite and degraded micas, and experienced low burial rates, with the result that the rocks bear a dominant mineralogical imprint from diagenetic zones II and III[30-32]

Do continental shelves export organic matter?

G. T. Rowe*, S. Smith*, P. Falkowski*, T. Whitledge*, R. Theroux†, W. Phoel‡ & H. Ducklow§

* Oceanographic Sciences Division, Department of Applied Science, Brookhaven National Laboratory, Upton, New York 11973, USA

§ University of Maryland, Center for Environmental Studies, Cambridge, Maryland 21613, USA

It has been suggested that biological production and consumption of organic matter is not balanced in coastal marine ecosystems[1,2]. If, as suggested, 90% of the phytoplankton produced during the spring bloom period were exported, excess organic carbon would be sequestered on the continental slope below the permanent thermocline. Here we summarize the shelf-edge exchange processes (SEEP) experiment, designed to test the export hypothesis. The absence of a positive imbalance in the organic carbon budget, reinforced by modest sediment deposition and biomass on the continental slope, led us to reject the concept. Only a small fraction of continental shelf phytodetritus is exported; that not consumed in the spring is for the most part used on the continental shelf during the ensuing stratified season The original hypothesis failed to recognize the contribution of pelagic microbial consumption and the lag in coupling between seasonal production and consumption processes.

Table 1 Moored sediment trap (MST) flux

	Date	Mass flux (mg m^{-2} d^{-1})	C (mg^{-2} d^{-1})	N (mg m^{-2} d^{-1})
MST 1	25 Feb - 5 March 1984			
70 m o b *		1,240 ± 198	54 ± 6	6 ± 1
10 m o b		5,450 ± 467	199 ± 44	20 ± 7
MST 2	5-31 March 1984			
70 m o b		1,810 ± 239	110 ± 28	12 ± 5
10 m o b		3,815 ± 418	159 ± 18	19 ± 4
MST 3	4-7 April 1984			
70 m o b		2,298 ± 240	140 ± 12	6 ± 4
10 m o b		2,748 ± 624	107 ± 16	1 ± 1

Data from SEEP I (150 m, west line locality W12 shown on Fig 1) Values are mean ± s d
* m o b, metres off bottom

The data we present come from a restricted area of the continental shelf of the eastern United States south of New England, which extends from longitudes 70°30′ to 72°30′ W, and includes the area between the coastline and the outer edge of the continental shelf from Martha's Vineyard south to Long Island (Fig 1) Two transects of moorings were instrumented with current meters, transmissometers and internally recording fluorometers[3,4] between February and April 1984 Sediment traps[5] were moored at locality W12 (Fig 1) during this period, and at the deeper moorings on the east line[6] throughout the remainder of the year Estimates of standing stocks and a variety of biological rate measurements were made during 24-48 h periods in shelf and slope water on both lines (Fig 1) between late February and mid-April 1984 Measurements over similar periods were made during July 1983 On the basis of the original hypothesis these data should have shown that annual net primary production appreciably exceeded consumption on the continental shelf, that biogenic particles or plant pigments had a net offshore flux, and that intensified organic carbon deposition was reflected in the sediments or the biota on the continental slope

The main aim of our work was to study the shelf carbon budget and to search for an imbalance betweeen primary production and heterotrophic use within the study area (Fig 1) Primary productivity was estimated by measuring ^{14}C-labelled assimilation during incubations aboard ship[7], and the consumption of phytoplankton carbon was estimated by summing respiration and secondary production of macrozooplankton[8-10], the benthic community[11,12] and pelagic bacteria[13,14] Microzooplankton were not included Zooplankton grazing was estimated from gut clearance rates[10] and known relationships between feeding rates, body size and food concentration[9] Bacterial respiration and production were based on labelled thymidine incorporation[13] and NH$_4$ regeneration rate measurements using ^{15}N-labelled substrates[14] Use of organic matter by the benthic biota was assumed to be by respiration and secondary production of the macrofauna[15] Respiration, the sum of anaerobic microbial metabolism and oxygen use, was estimated from oxygen use *in situ* in benthic chambers placed on the bottom by scuba divers and by ship-board incubations of the sediment cores[12] Sulphate reduction, nitrate reduction and organic carbon accumulation in shelf sediments may also contribute to carbon fluxes[12], but were not included here Although total benthic standing stocks were measured[12], we include here only the secondary production of the macrofauna based on established production to biomass ratios[15,16] and measured biomass of the macrofauna[17,18] Secondary production of the meiofauna and benthic bacteria were not included

The critical issue is the comparison of phytoplankton production rate with the total rate of consumption of organic matter

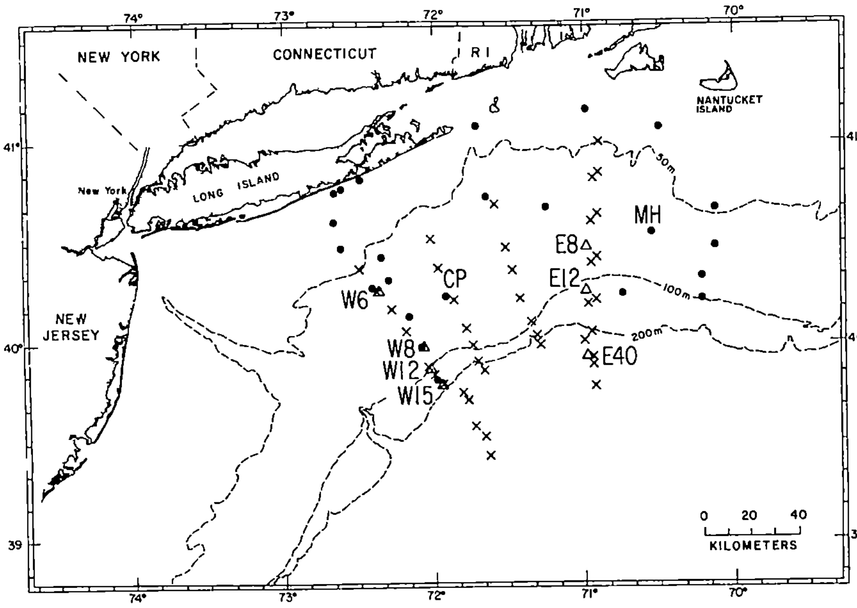

Fig 1 Location of SEEP experiment, east and west lines Time series were conducted at the triangles Sediment traps were located at W12 ●, Locations of sediment oxygen demand measurements, ×, locations of core or grab samples

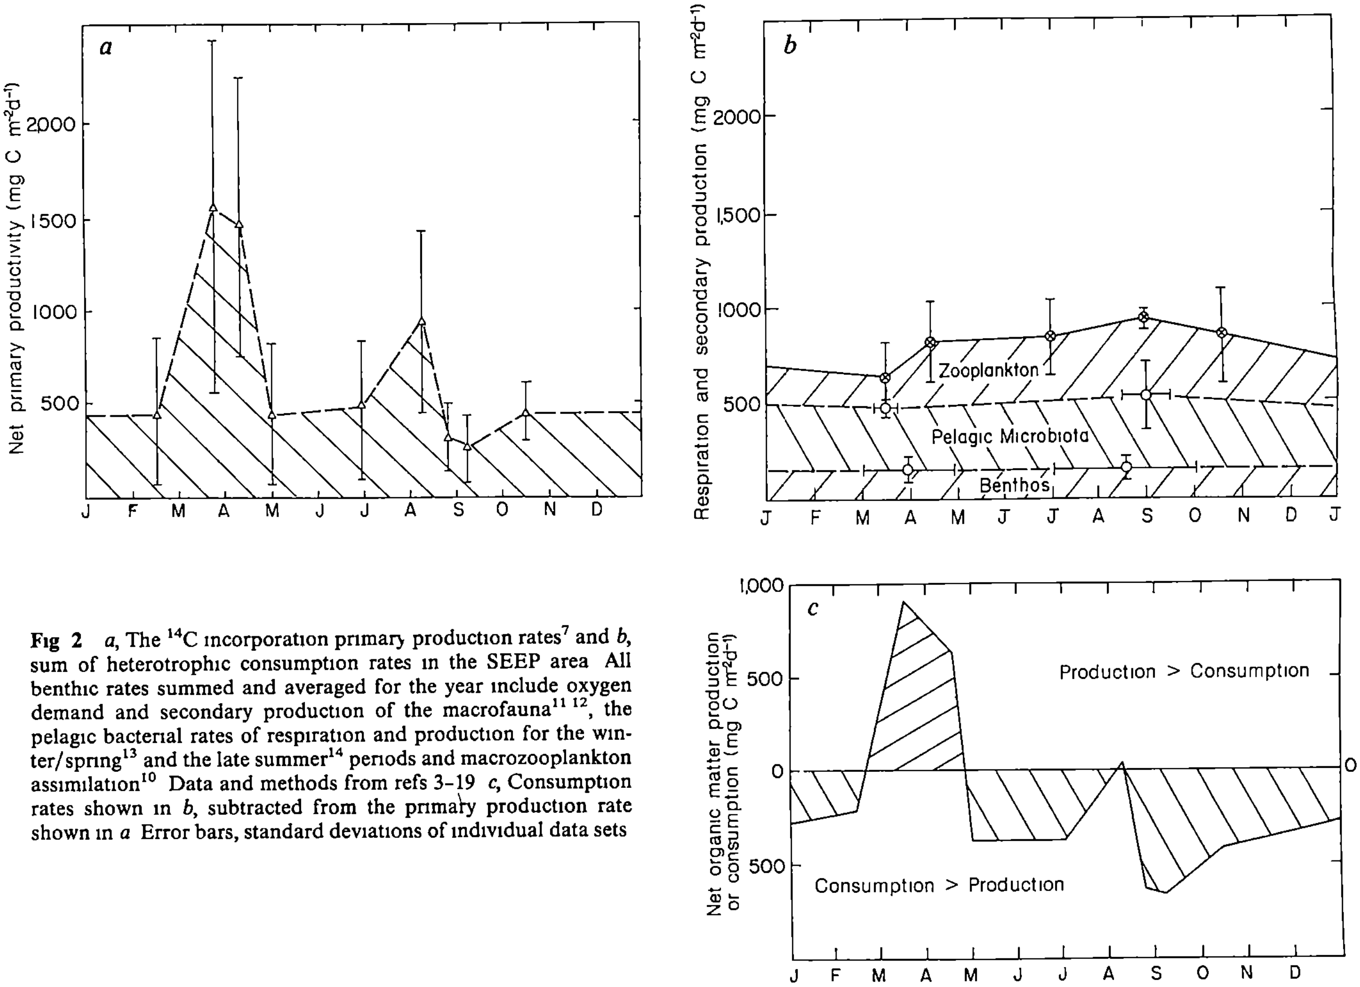

Fig 2 *a*, The ^{14}C incorporation primary production rates[7] and *b*, sum of heterotrophic consumption rates in the SEEP area All benthic rates summed and averaged for the year include oxygen demand and secondary production of the macrofauna[11 12], the pelagic bacterial rates of respiration and production for the winter/spring[13] and the late summer[14] periods and macrozooplankton assimilation[10] Data and methods from refs 3-19 *c*, Consumption rates shown in *b*, subtracted from the primary production rate shown in *a* Error bars, standard deviations of individual data sets

We have plotted the two separately over the course of a year (Fig 2*a*, *b*) The seasonal contrast is obvious on subtraction of integrated consumption from production (Fig 2*c*) This suggests that carbon fixation was predominant in the spring but that total remineralization and secondary production were the most significant processes during the rest of the year The results presented in Fig 2*c* provide no evidence to support the hypothesis that significant quantities of organic matter are available for export An annual manifestation of the intense heterotrophic activity following the bloom is the recurrent hypoxia experienced in the mid-Atlantic bight every year during stratified periods[19]

The budgeting approach undoubtedly suffers from some inaccuracies due to imprecision in each component The ^{14}C method may underestimate primary productivity (Fig 2*a*) if there is a loss of smaller photosynthetic picoplankton[20] Consumption (Fig 2*b*), on the other hand, does not include microzooplankton But as the microzooplankton consume the picoplankton as well as bacteria, the two omissions could to some degree cancel each other out[21] Sediment anaerobic respiration that is not incorporated into the measured total sediment oxygen demand (a distinct possibility if sulphide forms pyrite or is otherwise immobilized[12]) has also not been taken into account In spite of the limitations of our data set, the negative imbalance in the carbon budget (Fig 2*c*) cannot be considered justification for accepting the export hypothesis

Fluxes of organic carbon into sediment placed on the west line (Fig 1) also provided little evidence for accepting the hypothesis One mooring array of two traps was set for three different periods between 25 February and 7 April 1984, within continental slope water but underlying continental shelf water (locality W12 on Fig 1) Extensive particle export by sinking through or mixing across the shelf-slope front should be reflected in the traps, but the average rate of organic carbon flux to all traps (Table 1) was only 128 mg C m^{-2} d^{-1} ($\sigma = \pm 45$), or about 10% of the integrated euphotic zone primary productivity ($\sim$1 5 g C m^{-2} d^{-1}, $\sigma = \pm 0$ 76) at that time[7] This small fraction of the overlying net primary productivity was about what would be expected from direct vertical transport[22,23] and was below what we would expect if 90% of the net primary production during the spring bloom was exported to this depth[1,2] If only 50% of the net productivity was exported from a 100 km-wide continental shelf, and concentrated on a 30 km-wide continental slope, we would expect the organic carbon particle flux to be $\sim$1-2 g C m^{-2} d^{-1}, which is ten times greater than that sampled by the traps (Table 1)

Concurrent investigations of the transport of plant pigments and the characteristics of the sediments and biota of the continental slope support the above conclusions Although fluxes into sediment traps lower on the slope were greater near bottom than in the water column, the flux rates were far less than those we measured (Table 1) adjacent to the shelf-slope front[6] The moored fluorometers documented rapid sinking and extensive along-shore advection of biogenic particles Although some equivocal evidence suggested a net offshore transport may have occurred on the shelf, there was no evidence that appreciable material crossed the shelf-slope front[4] Cross-front exchanges of water between distinct shelf and slope water masses were very limited during the spring[24], although turbulent mixing may have been accentuated at the bottom by internal waves[25] An exchange of water of $\sim$20% across the front as it moves from Cape Cod to Cape Hatteras, based on salt and nitrate budgets[7], could be accounted for by this bottom mixed-layer exchange[25]

The logic behind extensive organic carbon export has been questioned before[26,27], but our data graphically illustrate that seasonal coupling and pelagic microbial activity[28] make the idea untenable Our results do not support the suggestion that an appreciable fraction of the global missing carbon is on continental slopes[1], but they do not exclude the possibility that most of the carbon on continental slopes was due to shelf export, albeit at a relatively slow rate Although our rejection of the hypothesis applies to the north-west Atlantic SEEP area in particular, it is important to ask how our conclusions might apply to other shelf ecosystems At higher latitudes, for example, colder water may depress microheterotrophic activity[29] The export and fate of carbon from narrow shelves where primary production is enhanced by external sources of 'new' nutrients[2,30,31] remains to be assessed

This work was part of continuing studies of coastal zone ecosystems by the Office of Health and Environmental Research, US Department of Energy (contract DE-ACO2-76CH00016), and the Northeast Fisheries Center, NMFS/NOAA We thank our collaborators in the SEEP experiments, as well as the officers and crew of the RV *Oceanus*

Identification of novel widely distributed sedimentary acyclic sesterterpenoids

J. N. Robson & S. J. Rowland

Department of Environmental Sciences, Plymouth Polytechnic,
Drake Circus, Plymouth, Devon PL4 8AA, UK

Isoprenoids, the general class of natural products biosynthesized from isoprene units, are abundant in nature. Many isoprenoids are also found in sediments, sedimentary rocks and crude oils where they have proved useful as 'chemical fossils' of biological activity and as indicators of geothermal stress[1]. However, acyclic isoprenoids with 25 carbon atoms—so-called sesterterpenoids—have been reported only rarely in the biosphere and the geosphere. Indeed, the only acyclic sesterterpenoids of confirmed structure reported in sediments are of pentamethyleicosane structural isomers (Fig. 1, carbon skeleton I). For example, 2,6,10,14,18-pentamethyleicosane has been proposed as a marker for halophilic bacteria and the 2,6,10,15,19-isomer (I) as an indicator of methanogens[2]. We have now identified a group of novel sesterterpenoids that are major components of the hydrocarbons of recent freshwater, marine and hypersaline sediments from many different parts of the globe. Because they have unusual structures, these sesterterpenes show promise as a new class of biological marker compounds.

Over the past 10 years many workers (Table 1) have reported the presence, in recent sediments, of a group of C_{25} hydrocarbons of unknown structure The compounds are abundant and are very widely distributed, for example, they are the major hydrocarbons present in sediments from a New England salt marsh, Narragansett Bay (USA)[3], North-east Gulf of Mexico[4], the Peru upwelling region[5], Shark Bay, Western Australia[6] and the Ebro River, Spain[7] The same compounds have been detected in aquatic filtering organisms and in sediment traps suspended in the water column[7-10] and recently a C_{25} diene has been detected in field specimens of the green alga, *Enteromorpha*[11] Numerous structures have been proposed for these C_{25} compounds (see Fig 1, skeletons II-V)[7,11,12] although no structure has been confirmed The electron impact mass spectrum and gas chromatographic Kovats Index (KI) of the parent C_{25} alkane[12,13] and ozonolysis of a C_{25} monoene[6] suggest structure II as the most likely skeleton This is supported by synthesis of a co-occurring

* The same compounds have been found in marine filtering organisms[8], an alga[11] and certain crude oils[25]

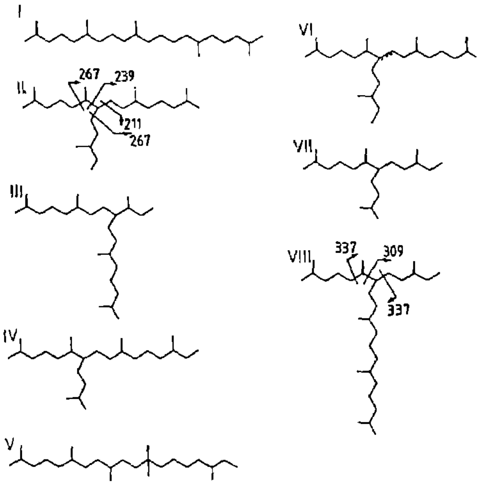

Fig 1 Isoprenoids, carbon skeletons I-VIII

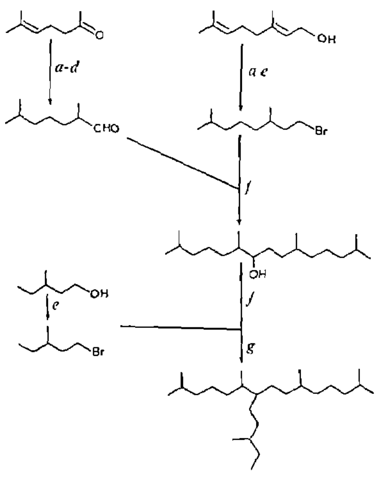

Fig 2 Synthetic scheme for alkane II and alkenes VI All products characterized by ^{1}H NMR mass and infrared spectroscopy The second Grignard reaction (f) was repeated in improved yield (82%) by use of CeCl$_3$/Mg (ref 29) a, H$_2$,PtO$_2$,hexane, b, BrCH$_2$Br,Mg, c, B$_2$H$_6$,THF,H$_2$O$_2$, OH d, (COCl)$_2$,DMSO, e, HBr/H$_2$SO$_4$, f, Mg,THF, g, POCl$_3$,Pyr

C_{20} alkane (assumed to be pseudohomologous with the C_{25} alkane)[14] Synthesis of V has shown this structure to be incorrect[12] and attempts to isolate the C_{25} alkenes by argentatious thin layer chromatography in quantities large enough for spectral characterization have been unsuccessful[15]

A mixture of five monoenes related to alkane II was synthesized in good yield from readily available starting materials by the scheme outlined in Fig 2 Catalytic hydrogenation afforded the alkane The electron impact mass spectrum of the synthetic alkane II is shown in Fig 3 The spectrum, which is virtually identical to that of the sedimentary alkane[12] contains small but characteristic ion doublets at *m/z* 210,211, 238,239 and 266, 267 assigned to fragmentation about the C7-C8, C6-C7 and C5-C6 (and C7-C1') bonds (structure II) The KI value for both synthetic and sedimentary alkane is 2,109 (DB-1, 40-290 °C at 4 °C min^{-1}) These data confirm that the C_{25} alkenes and alkane identified in many previous studies (Table 1 and ref 11) possess the 2,6,10,14-tetramethyl-7-(3-methylpentyl) pentadecane skeleton (structure II) Mass spectra of the synthetic monoenes (Fig 1, structure VI) were characterized by even mass ions at *m/z* 154,196,210 (weak), 224,266,280 and 350(M +) but none was identical to the spectra of any of the sedimentary monoenes This is further indirect evidence that the sedimentary alkenes may indeed contain a methylene double bond as suggested previously from ozonolysis[6] and nuclear magnetic resonance (NMR)[8] In sediments from Puget Sound[12] and Dabob Bay[9], Washington State (USA), the C_{25} hydrocarbons co-occurred with the C_{20} alkane (now known to be structure VII in Fig 1[11]) and a C_{30} alkene of unknown structure but which from retention index measurements was considered to be pseudohomologous with both structures VII and II when hydrogenated Given the structural relationship between VII and II demonstrated in the present study, it is reasonable to speculate that the C_{30} alkene is VIII (Fig 1) This is consistent with the mass spectrum in that fragmentation about the C6-C7, C5-C6

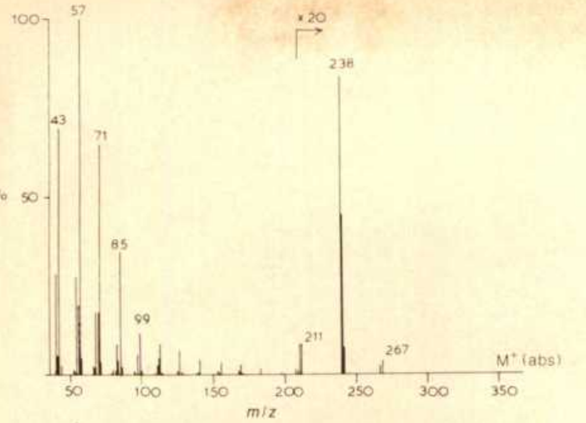

Fig. 3 Electron impact mass spectrum of synthetic II. Gas chromatography mass spectrometry conditions: Kratos MS25, 30 m × 0.3 mm CPSil 5 fused silica column, 40–300 °C at 4 °C min^{-1}. He carrier, 40 eV.

and C7–C1 bonds would produce the ions observed at m/z 308,309; 336,337 (structure VIII). Thus, the abundant sesterterpenes appear to be the major and most commonly occurring components of a new class of terpenoids comprising $C_{20,25,30}$ and possibly other[6], hydrocarbons.

These highly branched hydrocarbons have already proved useful as environmental indicators. For instance, variations in their abundance in sediments have been successfully used to designate distinct chemogeographic regions. Dunlop and Jefferies[6] were able to classify oceanic and hypersaline sedimentary basins in Western Australia on this basis and Requego and Quinn[15] were able to show that the geographical variations of some of the alkenes reflected the distribution of marine organic matter in the estuary of Narragansett Bay, USA. Now that the structures of the C_{20} and C_{25} hydrocarbons have been established and one possible source organism proposed[11], future studies may be based on a firmer understanding. Further synthesis and incubation of synthetic ^{14}C-labelled analogues should help to elucidate the longer term sedimentary fate of these new biological markers.

Finally, the unusual structures of these molecules suggest that they may have a specific role in the lipid biochemistry of the source organisms. This has proved to be the case for other unusual isoprenoid lipids. For instance biphytanyl isoprenoid ethers act as rigidifiers in the cell membranes of archaebacteria[16] and are therefore of interest to biologists, biochemists and geochemists. Further study of the present multi-branched lipids may benefit from a similar multidisciplinary approach.

Ostrich ancestors found in the Northern Hemisphere suggest new hypothesis of ratite origins

Peter Houde

Division of Birds, National Museum of Natural History,
Smithsonian Institution, Washington, D.C. 20560, USA

Modern ratites (ostriches, rheas, cassowaries, emus, and kiwis) are flightless birds which have a palatal structure termed 'palaeognathous'[1] and are found on daughter-landmasses of the Mesozoic supercontinent Gondwanaland. It has been suggested[2–4] that a single flightless ancestor, widely distributed in Gondwanaland, gave rise to the various lineages of ratite birds. The temporal calibration of the DNA molecular clock is primarily based on the divergence of ratites, and depends on the validity of this hypothesis. Newly studied fossils suggest that the ancestors of ostriches are instead among a group of North American and European birds, the '*Lithornis*-cohort', that had the potential of flight and from which the kiwis may have arisen separately.

The *Lithornis*-cohort of fossils is a group of hen-sized, palaeognathous carinates which had the potential of flight and are found in Palaeocene and Eocene deposits in North America and Europe[5]. The group includes *Lithornis*, *Paracathartes* and a genus I will refer to here as the 'Green River palaeognath' ('GRP'). They are the closest relatives of the ratite birds known to have had the capacity for flight, closer than the palaeo-

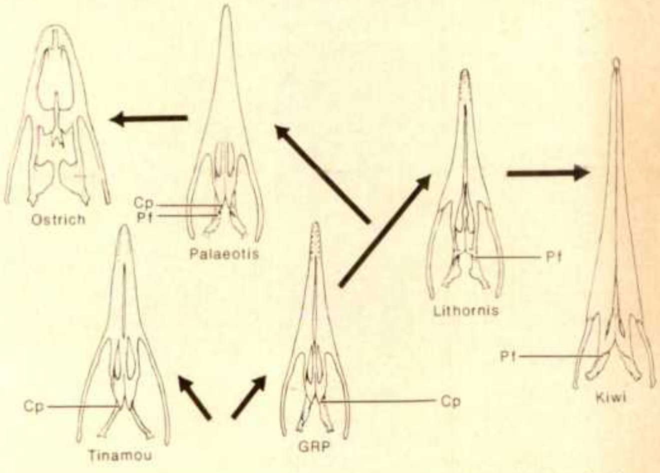

Fig. 1 Grades of evolution in the palatal complex of bones in the fossil and extant palaeognathous birds: tinamou (*Tinamus*, drawn from Smithsonian specimen USNM 345738); 'Green River palaeognath' (drawn from USNM 336103); *Lithornis* (drawn from USNM 391983; agrees with *Paracathartes*, USNM 391984); *Palaeotis* (drawn from HLMD Me 7530); kiwi (drawn from USNM 19025) and ostrich (drawn from USNM 224852), not to scale. The branching pattern does not necessarily represent the correct phylogenetic relationships of the fossil taxa but the monophyly of the ostrich and kiwi and the sister group relationship of tinamous is supported by molecular data[4]. Cp, caudal process of the palatine; Pf, pterygoid fossa.

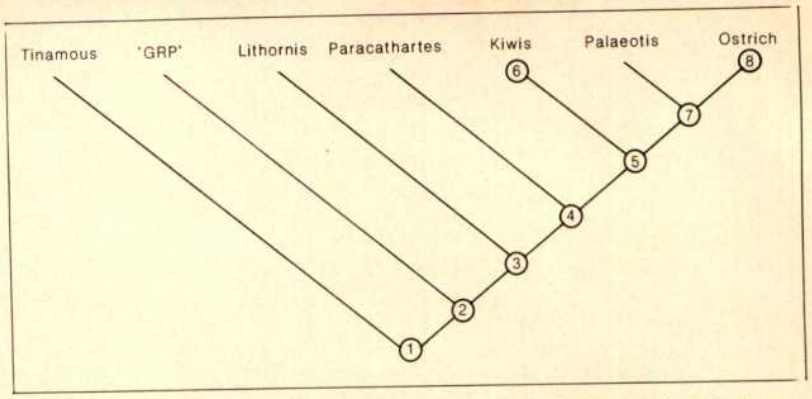

Fig. 2 Cladogram of some taxa of palaeognathous birds of unequal rank. Ratites without direct bearing to this discussion are omitted. Character suites are presumed to be apomorphous for all clades above 1. The caudal process of palatine is convergently absent in *Lithornis*, *Paracathartes* and Kiwis (not shown in cladogram). Character suites are: (1) palate palaeognathous, caudal process of palatine bone present, pterygoid narrow, vomer articulates with premaxillae, rhamphothecal grooves present, internarial septum small, splenial extends near to or forms part of mandibular symphysis, bill narrow, cervical vertebrae stout, ilioischiadic foramen open-ended, femur gracile, primary osteons of tibiotarsus predominantly oriented longitudinally, tibiotarsus with large lateral cnemial crest and well differentiated medial and lateral condyles, tarsometatarsus with pronounced, spherical intercotylar eminence, four toes present; (2) internarial septum large, pterygoid broad, quadrate fits into V-shaped notch in mandible, buttressed from behind by retroarticular process of mandible, scapula with styloid acromion, tarsometatarsus with large interosseous foramen, deeply concave anterior face and deeply excavated origin of extensor digiti IV brevis muscle; (3) pterygoid fossa present, vomer does not articulate with premaxillae; (4) primary osteons of tibiotarsus predominantly oriented transversely; (5) scapulocoracoid fused and sternum unkeeled, humerus long and spindly, with pronounced internal tuberosity and without pneumatic foramen, antebrachium short; (6) bill elongate, eyes reduced, tarsometatarsus without concave anterior face and excavated origin of extensor digiti IV brevis muscle, interosseous foramen small; (7) scapulocoracoid with large glenoid, acromion and acrocoracoid process, carpometacarpus with accessory foramina between each of the metacarpal bones, ilioischiadic foramen elongate, femur short, tarsometatarsus long, hallux absent (condition of quadrate mandible articulation unknown); and (8) pterygoid fossa absent, caudal process of palatine bone absent, V-shaped notch in mandible for quadrate absent, bill broad, cervical vertebrae elongate, femur short and robust, tibiotarsus with pronounced anterior cnemial crest and undifferentiated medial and lateral condyles, tarsometatarsus without spherical intercotylar eminence, concave anterior face and excavated origin of extensor digiti IV brevis muscle, interosseous foramen small and only two trochleae present.

gnathous tinamous (Tinamidae), the extant sister group of ratites[1,2,4,6]. *Palaeotis weigelti* was a crane-sized, flightless palaeognathous ostrich from the Middle Eocene of Germany, whose ancestry may be traced to the *Lithornis*-cohort. *Lithornis*[7], *Paracathartes*[8] and *Palaeotis*[9] were originally described from isolated, fragmentary remains and were mistaken for neognathous birds. Newly available, essentially complete skeletons that include the palatal bones (Fig. 1) now show unequivocally that these were palaeognathous birds. *Palaeotis* should not be confused with the incomplete fossils comprising the Asian family Ergilornithidae that have been suggested as ancestors of ostriches[10,11]. Ergilornithids were not palaeognathous birds.

The monophyletic origin of the *Lithornis*-cohort can be shown on the basis of shared derived characters (Fig. 2, character suite 2), all of which are absent in tinamous. Cranial (Fig. 1) and histological characters (Fig. 3) that characterize the living ratites evolved step by step in the phylogeny of the *Lithornis*-cohort. The large pterygoid fossa with no palatine process first appeared in clade 3, and the longitudinal pattern of bone osteons was replaced by the transverse pattern in clade 4 (Fig. 2). A higher-taxonomic group, comprised of the *Lithornis*-cohort, would thus be paraphyletic. That is, it does not include all of its evolutionary derivatives (the ratites), which have secondarily lost some of the distinguishing flight-related characters of the *Lithornis*-cohort.

An important element in the elucidation of ratite phylogeny is the fossil *Palaeotis*. Two skeletons of *Palaeotis weigelti* (specimen GM 4362, Geiseltalmuseum, Martin-Luther University, Halle a. Saale, GDR and specimen HLMD Me 7530, Hessisches Landesmuseum, Darmstadt, FRG) reveal all the characters that together define ratite birds,[1,2,6]. Derived characters that further distinguish *Palaeotis* as an ostrich (family Struthionidae) are

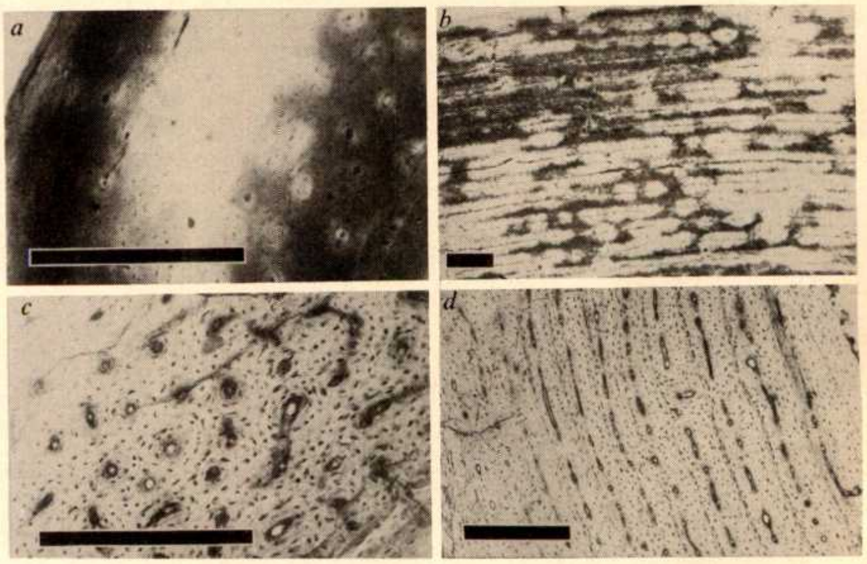

Fig. 3 Bright field photomicrographs of transverse lapidary thin sections through the same level (distal metaphysis) of *a*, tinamou (*Rhynchotus*, Princeton University PU 728); *b*, ratite (*Rhea*, specimen unnumbered); *c*, *Lithornis* (USNM 290554); and *d*, *Paracathartes* (USNM 361407), showing histological character states used in Fig. 2. Vascular canals appear as thin dark lines, spots, or circles on a light background of inorganic bone. Large dark regions are more opaque regions of bone, in which vascular canals may appear as light spots. Scale, 0.3 mm. The patterns formed by primary osteons are characteristically different in the leg bones of palaeognathous birds (tinamous and ratites) and neognathous birds (all other birds)[16,17]. The primary osteons in the tibiotarsus of *Lithornis* are predominantly parallel to the longitudinal axis of the bone, as in the tibiotarsus of the palaeognathous tinamous but unlike ratites and neognathous birds. Primary osteons in the tibiotarsus of *Paracathartes* are predominantly arranged in concentric rings that lie in the transverse plane of the bone, as in the tibiotarsus of ratites but unlike the tinamous and neognathous birds. Although the patterns of primary osteons could be evolved separately by unrelated birds, no correlation has been found between the pattern of primary osteons and flightlessness, ontogeny, or overall size among neognathous birds[18].

listed (Fig. 2, legend, character suite 7). Characters that are derived at the level of the *Lithornis*-cohort (Fig. 2, character suite 2) and primitively retained by *Palaeotis*, but not found in other birds, show that ostriches evolved from this group. Only *Palaeotis* and members of the *Lithornis*-cohort have palates with a caudal process of the palatine and a pterygoid fossa (Fig. 1), although both characters are not found together in *Lithornis*, *Paracathartes*, or the 'GRP'. *Palaeotis* forms an important link between the *Lithornis*-cohort and ostriches because all these characters are absent in large ratites, having been secondarily lost by all but kiwis.

Thus, ostriches were not only present in the Northern Hemisphere, but they may have evolved there long after the breakup of Gondwanaland. If so, then ostriches emigrated from Europe to Africa some time during the early or middle Tertiary, a dispersal route for which there are independent data for other taxa[12]. The hypothesis of ratite origins in Gondwanaland relies on the same route of dispersal, but in the opposite direction, to account for the presence of the recently extinct ostriches of Asia[2,13]. The absence of the *Lithornis*-cohort in early Tertiary deposits of the Southern Hemisphere does not conclusively prove that these birds lived only in the Northern Hemisphere at that time, but their absence there is conspicuous since *Lithornis* has been collected in relative abundance in the Northern Hemisphere for more than two centuries.

The vicariance biogeography hypothesis of ratite distribution requires that populations of flightless ratites were isolated as the result of geotectonic events and that the birds' own powers of dispersal were minimal. However, this hypothesis does not explain the occurrence of kiwis (Apterygidae) in New Zealand. Sibley and Ahlquist[4] could not reconcile the early (Cretaceous) divergence of the New Zealand plate from Gondwanaland with the relatively late (Eocene) divergence of kiwis from other ratite birds, based on DNA hybridization data. The fossils discussed here suggest that kiwis could have evolved directly from a palaeognath that flew to New Zealand and lost its power of flight independently of other ratite birds. Of the ratites, only kiwis retain primitive characters that are uniquely derived in the *Lithornis*-cohort (Fig. 1; Fig. 2, character suites 2 and 3), suggesting a relatively close relationship.

The far reaching implications of this study lie with the temporal calibration of the DNA hybridization molecular clock. Sibley and Ahlquist[4] postulated that the divergence of ostrich DNA from rhea DNA was initiated by, and therefore could be dated by, the spreading of the Atlantic seafloor. They have since[14] applied this calibration to a variety of other avian and mammalian taxa. With the simplicity of the vicariance biogeography hypothesis of ratite origins now challenged, one cannot accept this part of the calibration of the DNA molecular clock without at least some degree of scepticism. I have elsewhere[15] discussed problems with the four other data used to calibrate the DNA molecular clock.

Phospholipid vesicles as a model system for biomineralization

Stephen Mann*, John P. Hannington*

The tailoring of inorganic minerals such as iron oxides for functional use in biological systems for iron storage[1], structural support[2] and magnetoreception[3] involves biological regulation of crystal structure, particle size, morphology and crystallographic organization. The encapsulation of crystallochemical reactions within enclosed biological microvolumes enables control to be exerted over: (1) the chemical regulation, by passive or facilitated ion-transport, of localised supersaturation levels (2) the stereochemical requirements for ion-binding, redox and nucleation events at the organic matrix interface and (3) the spatial organization of crystal growth and morphology[4,5]. Matrix-mediated growth of inorganic materials has not been systematically investigated *in vitro* even though it may have applications in crystal engineering and materials science[6]. We have used phospholipid unilamellar vesicles of ~300 Å diameter to study membrane-mediated processes of iron oxide crystal growth. Intravesicular deposits differ in structure, morphology and size from precipitates formed from reactions in bulk aqueous solution. Mediating factors include vesicle shape and dimension, diffusion-limited processes of ion-transport and ion-binding at the curved lipid headgroup surface. These results help elucidate biomineralization and have technological relevance to the controlled synthesis of monodisperse sols with catalytic and magnetic properties.

Figure 1 illustrates the general reaction scheme adopted in our work. Unilamellar phospholipid vesicles with diameters of ~300 Å were prepared from phosphatidylcholine (17 mM) sus-

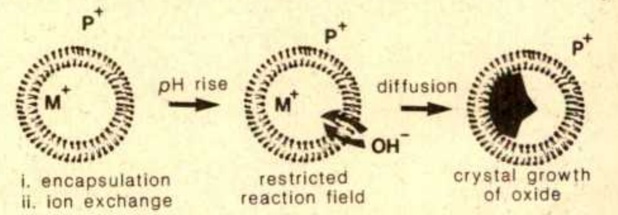

Fig. 1 Reaction scheme for membrane-mediated crystal growth of metal oxides in phospholipid vesicles. Cations (M^+) are encapsulated by sonication and replaced in the external phase by inert cations (P^+) by ion-exchange chromotography. This procedure results in organised restricted reaction fields for crystal growth. Increases in extravesicular *p*H result in OH^- influx and the nucleation and growth of metal oxides within the intravesicular space.

pensions at 4 °C in the presence of Fe(II) and/or Fe(III) solutions. Three preparative routes were investigated: encapsulation in the presence of (1) 100 mM $FeCl_3$ at *p*H 2.0, (2) 100 mM $FeCl_2 4H_2O$ at *p*H 4.0, (3) 50 mM $FeCl_2$ and 50 mM $Fe(NO_3)_3$ solution at *p*H 2.0. In each experiment, metal ions external to the vesicles were removed by ion-exchange chromatography (Na-form). Precipitation of Fe(II) and/or Fe(III) ions in the restricted reaction field delineated by the vesicle membrane was then induced by addition of aqueous NaOH (final *p*H, 12.0) to the extravesicular solution. A pale yellow colouration was noted in all the solutions after 30 min and it increased in intensity over several days. No precipitation was observed after bench centrifugation. By contrast, in similar precipitation reactions in the absence of vesicles, rapid precipitation of iron oxides was apparent. Unstained samples were air dried onto electron microscope grids and studied by transmission electron microscopy, selected area electron diffraction and X-ray microanalysis.

Electron micrographs of iron-containing vesicles before *p*H increase and precipitation showed that the intravesicular iron was not present as a simple salt solution but that extensive adsorption via ion-binding at the choline headgroups had taken place (Fig. 2*a*). Precipitation of the intravesicular iron after NaOH addition resulted in the formation of discrete, finely divided particles with mean diameters 35–40 Å (Fig. 2*b*). X-ray microprobe analysis of vesicles before and after precipitation showed the presence of Fe, P and Cl (trace). None of these elements was detected in background analyses of the electron microscope grid. Table 1 shows the results obtained from electron diffraction identification of these intravesicular deposits. Intravesicular Fe(III) solutions crystallized as poorly-ordered spherulitic geothite (α-FeOOH) whereas extended aggregates of ferrihydrite were formed in bulk solution. Precipitation of intravesicular Fe(II) solutions eventually produced discrete 30–50 Å diameter magnetite (Fe_3O_4) crystallites (Fig. 2*b*) whereas bulk oxidation produced a mixture of acicular lepidocrocite (γ-FeOOH) and goethite. Oxidation and precipitation of initial intravesicular Fe(II)/Fe(III) solutions formed poorly-ordered ferrihydrite in contrast with the crystallization of 100–500 Å magnetite particles in the absence of vesicles.

These results can be rationalized in terms of the control by the vesicle membrane on the rate of OH^- diffusion into the intravesicular space. We have shown elsewhere[7] that the influx of hydroxyl ions into phospholipid vesicles is critically related to the efflux of counter-anions from the intravesicular volume. The net rate of OH^- diffusion and hence the rate of iron oxide formation will be dependent on the efflux rate of the slower-moving chloride anion[8]. The rate of intravesicular Fe(II) oxidation, which is dependent on the rate of increase of intravesicular *p*H, has been followed spectrophotometrically by measurement of the Fe(III) absorption band at 420 nm. Whereas bulk oxidation at neutral or alkaline *p*H is rapid and follows overall third-order kinetics at constant $[O_2]$ (ref. 9), intravesicular Fe(II) oxidation shows overall first-order behaviour ($k = 3.7 \times 10^{-7}\ s^{-1}$) (Fig. 3) indicative of a diffusion-controlled mechanism.

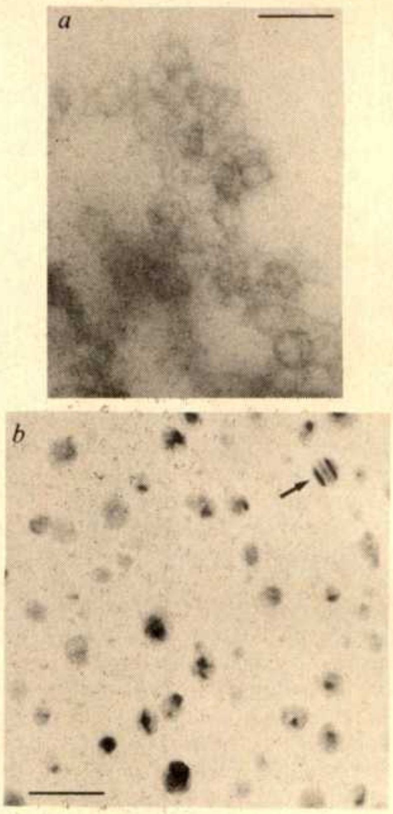

Fig. 2 *a*, Transmission electron microscope (TEM) image of phospholipid vesicles containing Fe(III) ions at *p*H 2.0. The binding of Fe(III) at the charged headgroups results in the *in situ* staining of the inner membrane surface. Bar, 60 nm. *b*, High magnification TEM image of intravesicular magnetite particles. Some particles show electron dense banding (arrow) which may arise from domains in twinned orientation or from diffraction contrast due to local crystal bending. Bar, 15 nm.

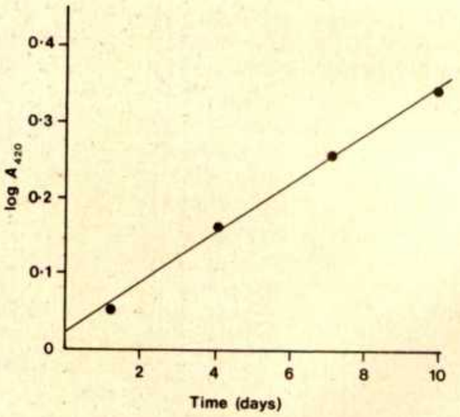

Fig. 3 Plot of log absorbance at 420 nm (A_{420}) against time for the intravesicular oxidation of Fe(II) solutions. The linear plot represents an overall first-order rate dependence. Samples were stored in the dark at 4 °C between readings. TEM studies showed minimal evidence of vesicle degradation over the course of the kinetic experiments.

These kinetic restrictions favour the formation of thermodynamically stable products such as geothite from Fe(III) solutions, rather than ferrihydrite which is formed under conditions of rapid precipitation. In addition, the retardation of the rate of intravesicular Fe(II) oxidation due to the slow increase in intravesicular *p*H favours the formation of mixed valence oxides such as magnetite whereas rapid oxidation at high *p*H in bulk solution generates hydrous iron(III) oxides such as goethite and lepidocrocite. The formation of intravesicular ferrihydrite rather than the bulk precipitated magnetite from 1:1 Fe(II)/Fe(III) solutions reflects a similar mediation of crystal growth by the membrane. The slow increase in intravesicular *p*H will allow oxidation and favour the preferential precipitation of the Fe(III) component at acid *p*H values.

Finally, particle sizes of the above intravesicular products are determined by the vesicle internal diameter and the encapsulation efficiency. In the experiments, assuming a simple salt solution and 100% encapsulation efficiency, ~2,000 Fe irons would be present per vesicle. This would result, for example, in intravesicular magnetite particles of 25 Å diameter. Our particles are slightly larger than this, which can be accounted for by additional ions arising from saturation binding of Fe at the headgroup sites (~1,500 on the inner surface, Fig. 2*a*). We also note that all the intravesicular particles are spherical or disk-shaped whereas bulk precipitates such as γ- and α-FeOOH are acicular. Nucleation of the intravesicular solids, induced at the lipid interface binding sites, is presumably such that the initial stages of crystal growth are partially constrained by the curvature of the vesicle membrane.

In conclusion, we have demonstrated the mediation of crystal-growth processes of iron oxides in the presence of organized membrane-bound assemblies. Future work will extend this aspect of membrane-mimetic chemistry to investigate the role of headgroup spacing, charge density and curvature on the nucleation and crystal growth of inorganic solids which are biologically and industrially relevant.

A thylakoid processing protease is required for complete maturation of the lumen protein plastocyanin

Johan Hageman[*†], Colin Robinson[‡], Sjef Smeekens[*†] & Peter Weisbeek[*†]

Plastocyanin, a photosynthetic electron carrier functional in the chloroplast lumen, is synthesized in the cytosol as a precursor (preplastocyanin) with an amino-terminal transit sequence[1]. This transit peptide contains the information specifying import into and routing within the chloroplasts and is removed in at least two steps[2]. An intermediate is observed in the stroma after the transport of preplastocyanin through the chloroplast envelope; mature plastocyanin is present in the lumen, after transport over the thylakoid membrane. We show here that the stromal processing protease[3] is not responsible for both processing events. It cleaves the precursor protein only to the intermediate size and a novel protease located in the thylakoids processes this intermediate to the mature protein. This second protease recognizes the processing intermediate but not the precursor. Thus plastocyanin import involves cleavage at the intermediate processing site mediated by the stromal protease and then cleavage at the mature processing site mediated by the thylakoid protease.

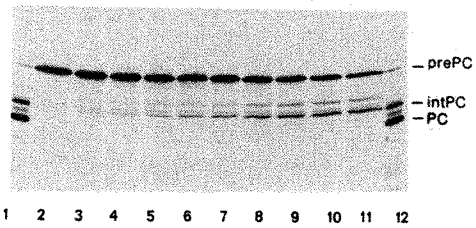

Fig. 1 Processing of plastocyanin precursor by stromal processing protease. Lane 1, import marker; lanes 2-11, incubation of plastocyanin precursor with partially purified protease for 0, 5, 10, 15, 20, 30, 40, 60, 90 and 120 minutes; lane 12, import marker.
Methods. Plastocyanin was synthesized in a wheat-germ system with RNA generated by *in vitro* transcription of the *Eco*RI-linearised pSPPC74 plasmid in an SP6 system[2]. The transcripts were capped by the addition of methylated cap ($m^7G(5')ppp(5')G$). The RNA was translated in a wheat-germ translation system in the presence of ^{35}S-methionine (1,000 Ci mmol^{-1})[14]. The stromal protease was concentrated ~350-fold from stromal extracts of pea chloroplasts as described[3]. The processing incubation at 27 °C contained 10 µl translation mix, 30 µl processing buffer (100 mM HEPES-KOH *p*H 8.5, 220 mM KCl, 5 mM $MgCl_2$) and 40 µl processing enzyme. At the times indicated, 8 µl aliquots were removed and put into a mixture of 32 µl H_2O and 40 µl sample buffer (125 mM Tris-HCl *p*H 7.6, 4% SDS, 5% sucrose, 5% 2-mercaptoethanol) and boiled for 2 min. The products were analysed by SDS-15% polyacrylamide gel electrophoresis using the Laemmli buffer system[15] and fluorography. Import marker: chloroplasts were isolated from young pea plants (cv Feltham First) as described[16] and finally taken up in import buffer (50 mM HEPES-KOH *p*H 8.0, 330 mM sorbitol) at a chlorophyll concentration of 1 mg ml^{-1}. In the import experiment 400 µl chloroplasts were incubated with 100 µl precursor plastocyanin translation mix, 25 µl 5× import buffer and 80 µl 200 mM methionine at 25 °C in the light[16]. After 60 min the chloroplasts were diluted with 10 ml import buffer and reisolated by centrifugation. The pellet was taken up in 600 µl sample buffer without protease treatment and boiled for 2 min. For each import marker lane, 15 µl of this mixture was used. The minor band between the processing intermediate and the mature plastocyanin may be an artefact as result of the length of the incubation.

Most chloroplast proteins are synthesized in the cytosol and subsequently transported into the organelle by a post-translational, ATP-dependent mechanism (for reviews see refs 4 and 5). The proteins are initially synthesized as larger precursors containing amino-terminal pre-sequences ('transit sequences') that are removed after import into the organelle. Transit sequences are believed to contain some, if not all, of the information specifying transport into the chloroplast and localization within the subchloroplast compartment[2,6,7]. Chloroplasts are composed of three membranes enclosing three discrete soluble phases—the intermembrane space, the stroma and the lumen. The proteins that are imported into the chloroplast have to cross one or more of these membranes; plastocyanin, a thylakoid lumen protein[8] must cross all three *en route* to its site of function. The import of preplastocyanin takes place in two stages[2], indicating that its transit sequence can be divided into an amino-terminal chloroplast-import domain and a thylakoid-transfer domain, each with its own processing site. We tried to determine whether the

Fig. 2 Amino-acid sequence of the transit peptides of the wild-type plastocyanin precursor (prePC)[1] and the substitute intermediate (PC58). The amino acids are numbered relative to the mature processing site. The intermediate processing site is around the isoleucine residue at −27.

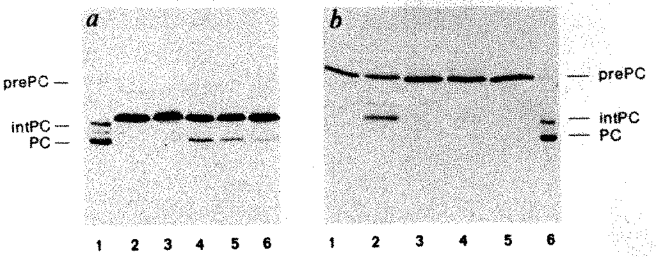

Fig. 3 A second protease is released from the thylakoids after Triton X-100 treatment. Incubation of PC58 (*a*) and plastocyanin precursor (*b*) with intact and Triton X-100-treated thylakoids. Panel *a*: lane 1, import marker; lane 2, PC58 translation mix; lane 3, incubation of PC58 with intact thylakoids; lanes 4–6, incubation of PC58 with thylakoids that were treated with 0.2, 0.5 and 1.0% Triton X-100 respectively. Panel *b*: lane 1, precursor plastocyanin translation mix; lane 2, incubation of preplastocyanin with intact thylakoids; lanes 3–5, incubation of preplastocyanin with thylakoids that were treated with 0.2, 0.5 and 1.0% Triton X-100 respectively; lane 6, import marker.

Methods. *In vitro* synthesis of PC58 was performed as described for plastocyanin precursor in Fig. 1 legend. The plasmid used is called pSPPC58. Thylakoids were isolated from isolated pea chloroplasts; intact chloroplasts at a chlorophyll concentration of 1 mg ml^{-1} in import buffer were pelleted by centrifugation and lysed by the addition of 20 mM Tris-HCl, *p*H 8.0, to the original volume. Aliquots of lysed chloroplasts were transferred to Eppendorf tubes and centrifuged in an Eppendorf centrifuge for 5 min at 4 °C. The pellet which contained the thylakoids was resuspended in the original volume of 20 mM Tris-HCl, *p*H 8.0. For the Triton X-100 treatment the thylakoids were pelleted again and taken up in solutions of 20 mM Tris-HCl, *p*H 8.0, containing the desired percentages of Triton X-100. The incubations (at 25 °C) contained 1 μl translation mix, 10 μl 20 mM Tris-HCl, *p*H 8.0, 10 μl processing buffer (see Fig. 1) and 70 μl untreated or Triton X-100-treated thylakoids. Reactions were stopped by adding 100 μl SDS-sample buffer followed by boiling for 2 min.

stromal processing protease is responsible for both the processing of the precursor to the intermediate and the intermediate to the mature form, or if not, what other proteases are involved.

Preplastocyanin was made by transcription *in vitro* of the *Silene* plastocyanin complementary DNA[2] in an SP6 vector[9], followed by translation of the RNA in a wheat-germ translation system. This procedure yields a single labelled band of precursor (Fig. 1 lane 2). The two minor lower relative molecular mass bands immunoprecipitate with plastocyanin antibodies (data not shown) and probably represent in-frame internal translation initiations at the methionine (ATG) codon at position −29 and at the isoleucine (ATC) codon at position −27 of the preplastocyanin transit sequence (see also ref. 2). The frequencies of these internal initiations vary between different wheat-germ systems (data not shown). The stromal processing enzyme was isolated from pea chloroplasts and purified ~350-fold[3]. As homologous size markers, mature plastocyanin and the processing intermediate were obtained from an *in vitro* import experiment with preplastocyanin (see Fig. 1 legend). The import marker lanes used in Figs 1, 2 and 4 show mature plastocyanin, a small amount of non-imported precursor and two intermediate bands the upper one of which represents the stromal processing intermediate[2].

Incubation of preplastocyanin synthesized *in vitro* with the partially purified stromal protease shows that the stromal processing protease is able to convert the precursor into a molecule the same size as the stromal intermediate (Fig. 1). It cannot be excluded that this processing occurs in two or more steps as the band between the precursor and the final processing product is consistently observed. The stromal protease however is not able to accomplish complete processing: even after prolonged incubation no mature protein is detected. (See also Fig. 4, lane 2.)

These results with *Silene* precursor plastocyanin differ from previous results obtained with barley and wheat plastocyanin[3]. We re-examined the processing of wheat plastocyanin precursor, using immunoprecipitated wheat plastocyanin mature protein as a reference during electrophoresis, instead of purified pea plastocyanin. This revealed that the protein that resulted from the processing with the stromal protease actually migrated more slowly than the immunoprecipitated mature plastocyanin from wheat (data not shown). The stromal protease therefore also processes the wheat plastocyanin precursor only to the intermediate size.

These results also imply that a second protease is responsible for the processing of the intermediate to the mature protein. Because the most likely location for this enzyme was the thylakoids, we incubated precursor protein with a thylakoid preparation. To release the putative protease from the thylakoids the membranes were disrupted by treatment with detergent[10]. Because of the possibility that precursor plastocyanin in addition to the precursor would not be recognized, a substitute intermediate protein was used to probe for the second protease. For the *in vitro* synthesis of this substitute intermediate a plastocyanin clone (PC58) was used which has had the initiator ATG codon removed by exonuclease digestion. Because of this, translation of *in vitro* transcribed *pc*58 RNA in a wheat-germ system starts at the first ATG, the methionine codon at position −29 downstream in the transit sequence (Fig. 2). Consequently PC58 protein is only a few amino acids longer than the stromal intermediate. PC58 is not imported into chloroplasts *in vitro* (data not shown). *In vitro* synthesis of PC58 yields one major labelled protein (Fig. 3*a* lane 2). The minor band above the PC58 protein probably represents an in-frame initiation at the isoleucine codon (position −55). The relative efficiency of initiation at this codon also depends on the wheat-germ extract used.

Formation of mature plastocyanin was not observed after incubation of PC58 protein or plastocyanin precursor protein with intact thylakoids (Figs 3*a*, lane 3; Fig. 3*b*, lane 2). PC58 was not processed at all, although the precursor was processed to the intermediate size. The latter processing was identical to that observed after incubation with stromal protease (Fig. 1) suggesting that the thylakoid fractions were not free from stromal contamination. Consistent with this, the SDS-polyacrylamide gels of the thylakoid preparation showed bands characteristic of ribulose bisphosphate carboxylase, the major stromal protein (not shown). PC58 is not processed by the stromal protease (data not shown) and therefore is not affected by stromal contamination.

Disruption of the thylakoid membranes by mild Triton X-100 treatment releases a protease activity that converts PC58 into a protein the same size as mature plastocyanin (Fig. 3*a* lanes 4–6). This processing activity is specific for the intermediate, as preplastocyanin is not processed at all under these conditions (Fig. 3*b* lanes 3–5), showing that the stromal protease contamination of the thylakoid fraction is completely inhibited by Triton X-100. The thylakoid protease is only moderately sensitive to this detergent. It can also be relased from the thylakoids by sonication (data not shown).

Finally, the combination of the stromal and the thylakoid protease is sufficient for the complete processing of preplastocyanin. After the incubation of the precursor first with the

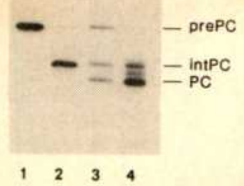

Fig. 4 Processing of plastocyanin precursor to the mature size by successive processing with a stromal protease and thylakoid protease. Lane 1, plastocyanin precursor translation mix; lane 2, incubation with stromal protease for 2 h; lane 3, incubation with stromal protease for 1 h followed by Triton X-100-treated (0.2%) thylakoids for 1 h; lane 4, import marker.

Methods. Plastocyanin precursor synthesized *in vitro* was incubated with partially purified stromal protease (see Fig. 1) for 1 h. Half was then incubated for 1 h with an equal volume of thylakoid vesicles treated with 0.2% Triton X-100 (see Fig. 3). The remainder was incubated for 1 h, after which samples were analysed by SDS-polyacrylamide gel electrophoresis followed by fluorography.

partially purified stromal protease and then with Triton X-100-treated thylakoids, a protein the same size as mature plastocyanin is detected (Fig. 4, lane 3). Prolonged incubation with stromal protease only resulted in a further decrease of the amount of precursor and an increase of the amount of intermediate (Fig. 4, lane 2), confirming that the stromal protease is not able to complete the processing. Processing of wheat preplastocyanin with this combination of proteases also results in complete processing to the mature size (data not shown).

The involvement of two distinct proteases in the processing of plastocyanin precursor to the mature size emphasizes the special nature of the transport route taken by nuclear-encoded proteins that are functional in the lumen. It also confirms the division of the plastocyanin transit sequence into a chloroplast-import domain and a thylakoid-transfer domain[2]. Partial processing of preplastocyanin by the stromal protease is consistent with the observation from the *in vitro* reconstitution experiments that the processing intermediate is found in the stroma, whereas the mature protein is found in the lumen[2]. The specificity of the thylakoid protease for the intermediate form suggests that this protease recognizes the plastocyanin transit sequence only after the removal of the chloroplast-import domain by the stromal protease. The determination of the exact location of the thylakoid protease is under investigation, and the first results on the purification show that the protease is water-soluble and retains activity on separation from the thylakoid membrane.

Plastocyanin, or more specifically the plastocyanin intermediate, is not the only protein that is imported from the stroma into the thylakoid lumen. A mechanism has to exist for lumen proteins made in the chloroplast too. By analogy with the proposed evolutionary origin of the chloroplast[11], this probably involves a prokaryote-like import mechanism. It will be interesting to determine whether plastocyanin and proteins synthesized in the chloroplast share import mechanisms or not, especially considering that the thylakoid-transfer domain remarkably resembles a prokaryote signal peptide[12]. The thylakoid protease would then function analogously to the signal peptidase[13].

Cholinergic neurones acquire adrenergic neurotransmitters when transplanted into an embryo

James Niles Coulombe & Marianne Bronner-Fraser

Developmental Biology Center and Department of
Developmental and Cell Biology, University of California, Irvine,
California 92717, USA

During development, cells become progressively restricted, until they reach their final phenotype. Differentiation was originally thought to be irreversible, but phenotypic plasticity has been observed in a variety of cell types, for example sympathetic neurones[1], the limb blastema[2] and some glial cell types[3]. A detailed description of the individual steps that lead to expression or reversal of phenotype is essential to understand the molecular events underlying cell differentiation. We examined whether ciliary neurones acquire adrenergic properties when exposed to a permissive embryonic environment. Cholinergic neurones were selectively labelled with a retrogradely transported marker and injected into chick embryos during active neural crest migration[4]. Four to five days after injection, some of the labelled neurones were found in 'adrenergic sites' and had developed catecholamine histofluorescence. The cells had thus accumulated adrenergic neurotransmitters even after differentiation into cholinergic neurones. This result shows that neurotransmitter plasticity occurs in cholinergic neurones and suggests that the neurotransmitter phenotype can be modified by the embryonic environment.

In the autonomic nervous system, both adrenergic and cholinergic neurones are derived from the neural crest[5]. In the differentiation of neural crest-derived neurones, the choice of neurotransmitter is a critical decision for proper autonomic function since the neurotransmitters used by sympathetic and parasympathetic neurones have antagonistic effects on their target organs. There is evidence that some neural crest cells may be fated to become cholinergic neurones; early migrating cranial neural crest cells have choline acetyltransferase activity[6] and acetylcholinesterase[7]. In addition, a monoclonal antibody to ciliary neurones recognizes a subpopulation of the neural crest cells in the mesencephalon[8]. After differentiation, the local environment may selectively promote survival of those neurones which contain the appropriate neurotransmitter, and/or instruct the developing cells to differentiate in the appropriate direction. Experiments showing that neurotransmitter choice in sympathetic neurones is labile even in post-mitotic cells[1] support the latter idea. Superior cervical ganglion cells (which normally produce catecholamines) produce acetylcholine[1,9–11] and form cholinergic synapses[12,13] when grown in the presence of a diffusible factor made by nonneuronal cells. Evidence for neurotransmitter plasticity in the autonomic nervous system is also found *in vivo* in the cholinergic sympathetic innervation to the sweat gland of the rat footpad[14–16] and in the cholinergic innervation of the iris following sympathectomy[17].

We examined neurotransmitter plasticity in cholinergic neurones, to ascertain whether cholinergic neurones are 'fated'

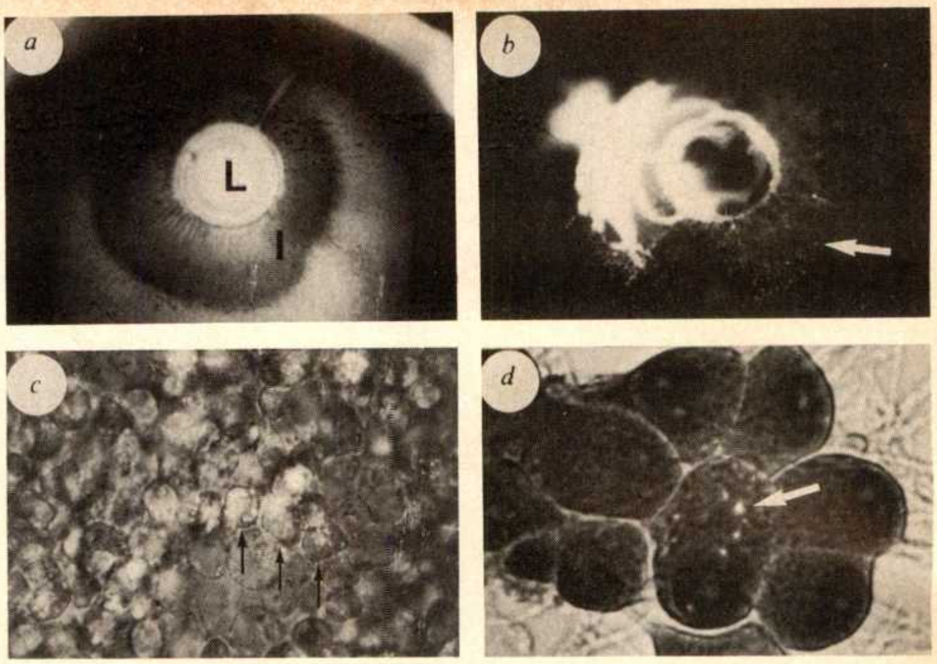

Fig. 1 Photomicrographs showing: *a*, *b*, the site of injection for retrogradely transported fluorescent latex microspheres in the iris region (I) of the eyeball. *c*, microsphere-labelled neurones in the ganglion. *d*, retrogradely labelled ciliary neurone. *a*, Transmitted light view of the iris region of a 6.5 day quail eye; L, lens (15×). *b*, Epifluorescence view of the same eye as *a*. Arrow, site where fluorescent latex microspheres filled the capillary bed of the ciliary body where axons from ciliary ganglion neurones terminate (15×). c, Combined fluorescence and bright field micrograph of a squashed ciliary ganglion showing fluorescent latex microspheres within neuronal cell bodies (596×). *d*, Bright field superimposed with fluorescence photomicrograph of a latex-based-labelled ciliary neurone (indicated by arrow) that has ChAT immunoreactivity (140×). All such neurones were found to be ChAT positive.

Methods. For labelling, the eyes were removed, leaving the ciliary ganglion in place at the back of the eyeball. The venous sinus (the canal of Schlemm), which supplies the ciliary ganglion and iris region with blood was severed ~3 mm proximal to the iris to avoid artefactual transport. Fluorescent latex microspheres (0.5–2.0 μm spheres, latex impregnated with rhodamine)[20] were pressure injected through the canal of Schlemm into the capillary bed that supplies the iris and ciliary body, the target sites for ciliary ganglion neurones. Because the venous sinus was severed, the neurones from the ciliary ganglion were only in contact with the latex microspheres at their growth cones and synapses, from which the microspheres were endocytosed and transported to the cell body. The eyeballs were incubated 8–10 h in a 95% oxygen, 5% CO_2 atmosphere at 37 °C in culture medium consisting of Eagle's minimum essential medium (Gibco) containing 15% horse serum, 10% chick embryo extract and 0.02% gentamycin sulphate. For ChAT immunocytochemistry, the microsphere-labelled ganglia were fixed in paraformaldehyde and picric acid, infiltrated with sucrose, and cryostat sectioned. Sections were dried onto gelatin coated microscope slides, and reacted overnight with primary antibodies against choline acetyltransferase (provided by Dr Miles Epstein) or tyrosine hydroxylase (Eugene Tech International Inc.). Antibody binding was made visible by treatment with biotin conjugated second antibodies, a biotin-avidin-horseradish peroxidase complex (Vectastain ABC), development with diamino-benzidine, and intensification with osmium. For cell counts, cell nuclei were stained with 4-6-diamidino-2-phenylindole dihydrochloride (DAPI).

to express only cholinergic neurotransmitters or labile with respect to neurotransmitter content. Previous investigators have transplanted cholinergic ganglia into presumptive adrenergic regions of the chick embryo[18]. In these transplants, the non-neuronal cells of the ganglia survived and synthesized catecholamines in the host adrenergic sites; the neurones, however, did not survive[19]. To test the transmitter plasticity of cholinergic neurones *in vivo* adequately, an experimental paradigm requires: (1) a transplantation method which supports neuronal survival; and (2) an unequivocal marker for the implanted cholinergic neurones. Here, we describe a new approach that meets these requirements.

To obtain a selectively labelled population of cholinergic neurones, we removed the eyes from 6.5 day quail embryos, leaving the ciliary ganglion in place at the back of the eyeball. Fluorescent latex microspheres were injected into a venous sinus supplying the iris and ciliary body, target sites for the neurones from the ciliary ganglion (Fig. 1). Microspheres were endocytosed by neuronal synapses and growth cones from ciliary neurones with processes at the target site, and were then retrogradely transported to the soma. The fluorescent latex microspheres, which were easily identified by their intense, punctate yellow-red fluorescence, have been shown to remain in the neuronal cell bodies for long periods of time and not to damage the neurone[20]. In 6.5 day old quail ciliary ganglia, ~15% of all cells were labelled with fluorescent microspheres. The labelled population represented ~20% of the neurones in the ganglia. The major advantage of this labelling technique is that only differentiated neurones, with processes at the target site, were labelled by retrograde transport.

To confirm that only neurones were labelled by the fluorescent microspheres, ciliary ganglia were dissociated and the cells were probed with an antiserum that recognized neurofilament proteins (Figure 2 and ref. 21). We classified a cell as labelled if it contained at least 5 fluorescent microspheres in its cytoplasm. Microsphere labelling was only found in cells containing neurofilament-like immunoreactivity. In addition, the microsphere-labelled cells had large cell bodies characteristic of neurones and many also had axonal processes.

An important assumption in our experiments is that the labelled neurones are cholinergic before transplantation. Four day old quail ciliary gangia have measurable choline acetyltransferase (ChAT) activity[22] and ciliary ganglion neurones *in vitro* form cholinergic synapses[23]. Recently, however, some tyrosine hydroxylase (TH) immunoreactive cells have been detected in avian ciliary ganglia[24]. Labelled ciliary ganglia were immunostained with antibodies against ChAT or TH to determine which of the neurotransmitter biosynthetic enzymes was present in labelled neurones. ChAT immunoreactivity (Fig. 1*d*) was found in all latex-bead-labelled neurones identified ($n > 1000$). In fact, all cells with the large cell bodies characteristic of neurones appeared to have ChAT immunoreactivity. Less than 1% of ciliary ganglion cells (estimated at 0.5% in chicken ciliary ganglia[25], and 0.8% in quail (unpublished data)) have TH immunoreactivity. No latex-bead-labelled neurones were detected among this population of TH-immunoreactive cells ($n = 104$).

Before implantation, the labelled ganglia were dissociated using conditions that promote neuronal survival in tissue culture[23]. The viability of the labelled neurones after dissociation was confirmed by their ability to regenerate severed axons and

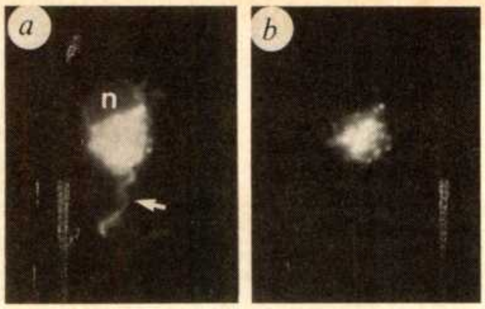

Fig. 2 Fluorescent photomicrographs of latex-bead-labelled ciliary ganglion neurones with anti-neurofilament antibodies. *a*, A ciliary ganglion neurone viewed with epifluorescence through a fluorescein filter has set neurofilament-like immunoreactivity. This cell has the large cell body and axonal process (arrow) characteristic of neurones. Due to fluorescence crossover, some latex microspheres could be seen through this filter set. Note the cell nucleus (n) 144×). b, The same neurone as in *a* viewed with a rhodamine filter shows numerous fluorescent latex microspheres in the cytoplasm (1440×). Diffuse signal is due to microspheres which were out of the plane of focus. Antibodies to neurofilament proteins were found to stain all cells containing fluorescent microspheres, suggesting that the microsphere-labelled cells were, in fact, neurones.

Methods. After labelling, ciliary ganglia were removed from the eyeball and cleaned of connective tissue and the ganglion capsule. The ganglia were then dissociated in 0.1% trypsin (Difco) in Modified Puck's Saline with glucose (MPG). Following trypsinization, the ganglia were mechanically dissociated by gentle trituration. For some experiments, the dissociated cells were filtered through a Nitex 15 μm screen. The dissociated cell suspension was fixed in 4% paraformaldehyde in 0.1 M phosphate buffer for 30 min at 22 °C. After washing, the cells were permeabilized in MPG containing 0.05% saponin with 5% goat serum for 30 min and reacted at 4 °C overnight with a rabbit primary antiserum (diluted 1:200) that specifically recognizes neurofilament proteins[21]. The cells were then washed and reacted with fluorescein-conjugated goat antibodies against rabbit immunoglobulin G (IgG) (diluted 1:20) for 1-2 hours at 37 °C.

to survive in culture. For some experiments, the ganglion cell population was enriched for neuronal cells by preplating[26]. The suspension containing labelled cholinergic neurones was implanted into the trunk somites of stage 12-18 chicken embryos using an injection technique[4], which reproducibly placed the cells on the ventral neural crest migratory pathway[27]. Embryos were incubated for an additional 4-5 days after injection, during which time some endogenous neural crest cells differentiated into catecholamine-containing cells[28]. The hosts were then rapidly frozen, processed for catecholamine-histofluorescence, and serially sectioned. During the 4-5 day incubation period, labelled neurones moved along the ventral neural crest pathway and collected around the dorsal aorta, where endogenous neural crest cells coalesce to form the adrenal medulla, sympathetic ganglia and aortic plexuses. Thus the labelled, dissociated ciliary ganglion neurones survived after implantation and were primarily located in or near sites normally populated by neural crest cells.

Injected embryos were examined for cells containing both fluorescent microspheres and catecholamines. We have identified, in nine separate embryos, a total of 33 microsphere-labelled ciliary ganglion neurones which also contained catecholamine histofluorescence (Figure 3*b*,*c*). Using a Feulgen stain, we have confirmed in several cases that the microsphere-labelled catecholamine-containing neurones also had the quail heterochromatin marker[29]. The number of labelled neurones containing adrenergic neurotransmitters represents ~5-10% of the microsphere-labelled neurones identified in section and ~50% of the labelled neurones that were incorporated into adrenergic structures. The other microsphere-labelled neurones were generally found near adrenergic cells but were not incorporated into adrenergic structures. Before injection no ciliary ganglion neurones contained catecholamines[25] or had a catecholamine uptake system[30]. Thus, some cholinergic neurones gained adrenergic neurotransmitters in the proper embryonic environment.

We observed a larger percentage of labelled neurones from ciliary ganglia in the adrenomedullary cords than in sympathetic ganglia. A similar distribution pattern to that of the labelled ciliary ganglion neurones is observed when inert latex beads are injected into the embryos[31]. Both the neurones and the beads may be moved to ventral sites by an environmentally controlled mechanism independent of cell motility. Only a fraction of the labelled neurones had catecholamine histofluorescence, and all of these were located in adrenergic structures such as the sympathetic ganglia or adrenomedullary cords. Localization in adrenergic structures may therefore be a prerequisite for the adrenergic phenotype. This suggests that the local environment, rather than the migratory process, influences the expressed phenotype of the neurones. A possible explanation for the small number of labelled neurones that were incorporated into host adrenergic structures may be that they are 'outcompeted' from these sites by endogenous neural crest cells. Because we have only examined the catecholamine content of the labelled ciliary ganglion neurones, our experiments cannot discriminate between uptake or synthesis of catecholamines. Neurones from ciliary ganglia *in vitro* do not have a catecholamine uptake system (refs 25, 30 and unpublished observations). Therefore, the labelled neurones have at least expressed biochemical systems for uptake and storage of catecholamines.

Control transplantations were performed to determine whether microsphere label could be passed to previously unlabelled cells after transplantation. Labelled ganglion cells were killed by repeated freeze/thawing, yielding microsphere-labelled ganglion-cell debris; the debris was then coinjected with an equal volume of a suspension of unlabelled live ciliary ganglion cells as in the experiments described above. In these controls, no cells containing multiple microspheres were identified. Individual microspheres were sometimes observed either in cells or extracellularly, but multiple microspheres were not acquired by unlabelled cells. This validates our selection of 5 microspheres as the criterion for labelling.

Thus, under appropriate conditions, cholinergic neurones can acquire an important characteristic of the adrenergic phenotype. Other investigators have observed that the environment encountered by neural crest cells can influence their subsequent differentiation. In quail/chick chimaeras, premigratory neural crest cells from presumptive cholinergic regions of the neural axis become adrenergic when grafted into the trunk[32]. In tissue culture, altering the environmental conditions can affect the differentiation of neural crest cells[33,34]. The culture environment can also induce explanted ciliary ganglion neurones to express some adrenergic characteristics; ciliary neurones *in vitro* can express immunocytochemically detectable tyrosine hydroxylase[24,25]. Similar results were observed *in situ* where some fibres from adult ciliary neurones apparently acquire tyrosine hydroxylase immunoreactivity after sympathectomy[17]. But, no catecholamines were detected in the ciliary neurones either *in vivo* after sympathectomy or *in vitro*, which contrasts with our findings.

Our results, together with the previous observations of the adrenergic to cholinergic transition[1,9-16], suggest that autonomic neurotransmitter plasticity is bidirectional. It remains to be determined whether the accumulation of catecholamines is due to uptake or synthesis, whether the transition can occur only in a defined period, whether cells reenter the cell cycle before expressing catecholamines and whether the labelled neurones can express both cholinergic and adrenergic traits simultaneously. Because transplanted cholinergic neurones can

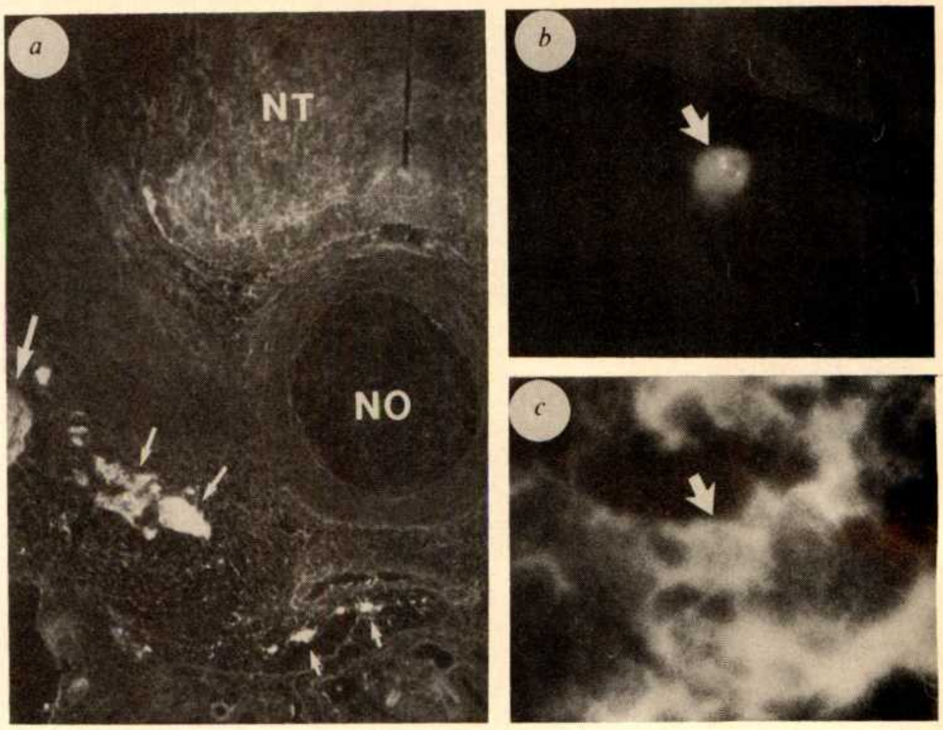

Fig. 3 Transverse sections through 7.5-day-old chicken embryos processed for catecholamine histofluorescence 5 days after labelled ciliary ganglion neurones were injected into the trunk somites. *a*, Low magnification of a transverse section through the trunk illustrating the sites where neural crest cells have formed catecholamine-containing derivatives. NT, neural tube; NO, notochord; arrows, sympathetic ganglia, adrenomedullary cells, and aortic plexuses (81×). *b*, A high power photomicrograph of the same embryo showing a retrogradely labelled neurone located in the adrenomedullary cords, viewed through a filter set designed for rhodamine fluorescence. Fluorescent latex microspheres, which have an intense punctate yellow-red fluorescence, can be visualized in the cell indicated by the arrow (890×). *c*, The same field as in *b* viewed through a catecholamine filter set, through which adrenergic cells are identified by their intense blue-green fluorescence. The microsphere-labelled cell (indicated by arrow) contains catecholamines and was part of a group of adrenergic cells located in the adrenomedullary cords (890×).

Methods. Embryos were rapidly frozen in liquid nitrogen-cooled isopentane, freeze-dried at −40 °C for ⩾4 days, equilibrated to room temperature and exposed to formaldehyde vapour for 1–2 h[35]. Fixed embryos were embedded under vacuum in paraplast, serially sectioned at 10 μm and placed dry onto albumin or acrylic adhesive coated microscope slides. Sections were covered with microscope immersion oil (Nikon) and examined at 800× under epifluorescent illumination. We confirmed that the same cell profile contained both microspheres and catecholamine histofluorescence using both rhodamine and catecholamine filter sets and examining the cell in a number of focal planes.

accumulate catecholamines, our results are consistent with a cell lineage model in which the neurotransmitter phenotype of autonomic neurones is strongly influenced by instructive cues from the local environment.

We thank Dr Scott Fraser for his helpful comments on the manuscript and Georgia Guillory and Jeffrey D. Pratt for technical assistance. This work was supported by USPHS Grant HD-15527-01 and by Basic Research Grant 1-896 from the March of Dimes.

Human immunodeficiency virus type 1 (HIV-1, HTLV-III/LAV), the retrovirus responsible for acquired immune deficiency syndrome (AIDS), shows a high degree of genetic polymorphism, particularly in the *env* gene[1–6]. We have examined sera from rabbits and guinea pigs immunized with gp130, a recombinant *env* glycoprotein[7], and sera from HIV-1-infected subjects[8], to test their capacity to neutralize a panel of genetically divergent HIV-1 isolates. The sera raised against recombinant antigen specifically neutralized the virus strain from which the *env* gene was cloned (HTLV-IIIB), but not an independent isolate (HTLV-IIIRF). One rabbit serum tested on seven isolates cross-neutralized two at lower titres. In contrast, human sera from Britain and Uganda, chosen for ability to neutralize HTLV-IIIRF, cross-neutralized six other

HIV-1 isolates. When serum and isolate were derived from the same subject, the serum was in some cases effective at slightly lower concentrations (higher titres). Human complement did not affect neutralization titres. These findings indicate that genetically diverse HIV-1 isolates carry both variable and widely conserved antigenic epitopes for neutralizing antibodies. The identification of shared epitopes may help the development of protective vaccines.

The production of a glycosylated recombinant envelope antigen of HIV-1 (gp130) by hamster CHO cells was recently described[7]. This recombinant antigen has at its amino-terminus 25 amino acids of the herpes simplex type 1 glycoprotein D, followed by amino acids 61–531 of the *env* gene of the HIV-1 isolate HTLV-IIIB (IIIB) representing most of the major envelope glycoprotein, gp120. This antigen is secreted by CHO cells. Rabbits and guinea-pigs immunized with partially purified gp130 in Freund's adjuvant neutralize the infectivity of the IIIB isolate and immunoprecipitate not only recombinant gp130 but also gp160 and gp120 of IIIB (ref. 7). In Table 1 we confirm the neutralization of the IIIB isolate by two different assays, but find no significant neutralization of a distinct, Haitian isolate, HTLV-IIIRF (RF).

To ascertain whether antisera raised against recombinant gp130 specifically neutralized only the HIV-1 strain from which the recombinant was derived, envelope pseudotypes of vesicular stomatitis virus (VSV) were prepared from seven different HIV-I isolates, and their sensitivity to neutralization was tested with rabbit anti-gp130 serum. In addition, twelve sera from British and Ugandan[9] subjects pre-selected for neutralizing activity to the RF isolate were screened, as was an enzyme-linked immunosorbent assay (ELISA)-positive Ugandan serum that was inactive for RF neutralization. Pre-immune rabbit serum, anti-HIV-1 ELISA-negative human sera and a VSV(HTLV-1) pseudotype were employed as negative controls.

Table 2 shows that the rabbit anti-gp130 serum specifically neutralized IIIB, cross-neutralized MN (ref. 1) and MA2 (ref. 10) isolates, but did not neutralize four other isolates. In contrast, the human anti-HIV-1 sera, whether British or Ugandan, cross-neutralized nearly all HIV-1 isolates, including two sera (British 23, 24) taken from subjects who were infected after receiving a single HIV-positive blood transfusion and who had no other

Table 1 Strain-specific neutralization of HIV-I by sera raised against recombinant *env* polypeptide gp130

2	50	—	50	—
3	50	—	50	—

Two methods were used to titrate the neutralizing activity of rabbit and guinea-pig sera to HIV-1 gp130, after heat inactivation at 56 °C for 30 min. The first assay measured surviving tissue-culture infectious doses (TCID) of HIV-1, when serum dilutions were mixed with 10^5 TCID in culture medium (RPMI-1640 with 10% fetal calf serum) for 1 h at 43 °C and dilutions of the reaction mixture were then added to 10^5 C8166 assay cells. The cultures were maintained for 7 days and the presence of large multinucleated syncytia was scored on day 4 and 7. HIV-1 end-point titrations ($TCID_{50}$) scored by appearance of syncytia in C8166 cells were equivalent to those scored by immunofluorescence of HIV-1 antigens in the cells or the presence reverse transcriptase in the medium of C8166 or H9 cells infected with HIV-1 (unpublished data). The neutralizing titre shown is the reciprocal of the highest dilution inactivating $\geq 90\%$ TCID of HIV-1. The second assay[8] used the neutralization of vesicular stomatitis virus (VSV) pseudotypes bearing the envelope glycoproteins of HIV-1. Serum dilutions were mixed with 200 plaque forming units (p.f.u.) of VSV(HIV-1) for 1 h at 43 °C before plating in 30 mm diameter wells on 2.5×10^5 adherent CCRF-CEM cells pretreated with DEAE-dextran. After adsorption for 1 h, 10^6 CCL64 mink cells were added, followed by an agar overlay 2 h later. VSV cytopathic plaques were counted 20–48 h after VSV(HIV-1) plating, and the neutralizing titre is expressed as the reciprocal of the highest serum dilution giving $\geq 80\%$ reduction of p.f.u. Pre-immune sera from the same animals had no neutralizing activity. The (−) sign indicates no significant neutralization with 1:9 serum dilution.

VSV(HIV-1) pseudotypes were prepared as described[8] for all 7 HIV-1 isolates. They were propagated in H9 cells except for Z129 in the K12 clone of HUT78 cells. Serial dilutions of heat-inactivated sera were reacted with 200 p.f.u. of VSV(HIV-1) and the surviving p.f.u. titrated as described for Table 1. VSV(HTLV-1) was grown in HOS/PL cells as described[13], and was used as a control to demonstrate the specificity of VSV(HIV-1) neutralizing activity.

known exposure to HIV-1. The Ugandan serum that was negative for RF neutralization failed to neutralize any isolate. It appears that the sera of humans infected with HIV-1 are more cross-reactive for neutralization than the rabbit anti-serum raised against gp130. However, as the neutralizing titre of the rabbit anti-serum was only 1/50 for the homologous virus (IIIB), a low degree of cross-reactivity might not have been detected. Higher titre anti-gp130 sera would merit investigation.

Indirect immunofluorescence techniques were used on H9 cells productively infected with IIIB, RF and ARV-2 to test whether the rabbit anti-gp130 serum recognized non-neutralizing epitopes of HIV-1. Positive results were obtained with each isolate with anti-gp130. It is clear, therefore, that some common epitopes on the virion envelope identifiable by membrane immunofluorescence are not targets for neutralization.

Table 2 also shows that VSV pseudotypes prepared with certain HIV-1 isolates (such as ARV-2) are generally more sensitive to neutralizing sera than other isolates (such as IIIB). This property does not appear to correlate with absolute VSV(HIV-1) titre, as all pseudotype preparations contained $\sim 10^4$ plaque-forming units per ml.

We previously reported[8] that some sera had high titres for weak neutralization (50% plaque reduction) but that sera taken from the same patients as the isolates (LAV-1, CBL-1) did not show preferential neutralization of their own isolate. However, sequence analysis has indicated that the *env* sequences of the four isolates tested show <3% nucleotide divergence. We therefore tested the neutralizing activity of sera against HIV-1 isolates from the same patients, using HIV-1 isolates that are known to be genetically polymorphic (Table 3). The data indicate that some virus isolates are more sensitive to neutralization by their autologous serum (for example, RF) and that some weakly neutralizing sera (for example, RUT) neutralize the autologous isolate best. But Z84 and Z129 were not neutralized by autologous sera.

The strong membrane immunofluorescence seen with some sera which show weak or no neutralizing activity against HIV-1 (ref. 8) suggests that non-neutralizing antibodies bind to virion envelopes. We therefore investigated whether complement enhanced the neutralizing activity of antisera directed to HIV-1 envelope glycoproteins. Our results indicate that neutralizing titres are not significantly enhanced by human complement (not shown).

Our experiments reveal the presence of both common and strain-specific epitopes in the target antigens for antisera responsible for the neutralization of HIV-1. The studies with recombinant gp130 (ref. 7) and VSV(HIV-1) pseudotypes indicate that the major viral envelope glycoprotein, gp120, is a target for neutralizing antibodies, but that does not exclude gp41 and possible *gag* gene products. Where the *env* sequences are known (IIIB, ARV-2 and RF), they show up to 15% nucleotide sequence divergence[3,4], and it is likely that the Zairian and Tanzanian isolates are even more divergent[5]. HIV-1, like the lentiviruses of ungulates[11], shows considerable genomic polymorphism, particularly in those regions of the *env* gene encoding domains not characteristic of oncoviruses[6].

Although some of the genetic variability exhibited by HIV-1 is reflected in divergence of neutralization antigens, there are insufficient data as yet to determine to what extent the variants have been immunologically selected. The human sera may be more cross-reactive than those from animals immunized with non-infectious antigen because of exposure to different epitopes, (1) through processing of newly made viral antigens, (2) opportunities for infection by multiple strains, and (3) the possible generation of variants during the course of infection[12]. Two serum samples were from subjects who had been exposed to HIV-1 on only one occasion (blood transfusion), but that does not exclude the possibility of infection with more than one strain present in the donor's blood. It is most unlikely that all the British and Ugandan sera would cross-neutralize American, Haitian, European and African strains through exposure to multiple, variable epitopes of viral antigen. We therefore conclude that certain neutralization antigens of HIV-1 are conserved between the diverse strains.

The variation of HIV-1-neutralizing antigens is in striking contrast to HTLV-1, for which neutralizing sera and virus isolates from Japanese, British West Indian and United States subjects are indistinguishable, though distinct from HTLV-2 (refs 13, 14). However, the neutralizing serotypes of avian leukosis viruses show considerable variation even within a single envelope subgroup[15,16], and different isolates of the bovine leukosis virus share some neutralizing epitopes of the gp51 envelope glycoprotein[17].

Our demonstration of conserved neutralization antigens, possibly those close to the binding site of gp120 to the CD4 cellular receptor[18-20] or other functionally conserved domains, may be important in the development of vaccines that elicit humoral and cellular immunity to HIV-1 infection. The strain specificity of the sera raised against recombinant gp130 reported here and those raised against purified gp120 of HTLV-IIIB (ref. 21) may indicate immunodominant determinants specific to the IIIB isolate. Further studies using monoclonal antibodies, and sera raised against different *env* constructs are in progress. By using a panel of VSV pseudotypes enveloped by glycoproteins of genetically and immunologically variant isolates of HIV-1, antisera raised against recombinant glycoproteins or synthetic peptides can be rapidly screened to identify those eliciting antibodies cross-reactive for neutralization.

We thank R. C. Gallo and M. Popovic for providing HIV-1 isolates, HTLV-IIIB, RF, MN and serum RF, and HTLV-1 transformed C91/PL and C8166 cells; L. Thiry and J. A. Levy for ARV-2 and ARV-4 viruses and sera; and D. Zagury for Z84 and Z129 viruses and sera. Human sera from Uganda were provided by R. G. Downing and N. K. Sewankambo. D. Whitby provided technical assistance. This study was supported jointly by the Cancer Research Campaign and the MRC. J.N.W. is supported by a clinical research fellowship from the Wellcome Trust.

Cytotoxic T lymphocytes recognize influenza haemagglutinin that lacks a signal sequence

A. R. M. Townsend*, J. Bastin*, K. Gould† & G. G. Brownlee†

* Nuffield Department of Clinical Medicine, John Radcliffe Hospital, Headington, Oxford OX3 9DU, UK
† Sir William Dunn School of Pathology, University of Oxford, South Parks Road, Oxford OX1 3RE, UK

A surprising feature of most cytotoxic T lymphocytes (CTL) responding to influenza infection is that they recognize the unglycosylated (non-transmembrane) proteins of the virus, including the nucleoprotein[1–4]. Recognition of cells that express nucleoprotein by CTL does not depend on a definite signal sequence within the protein[5], and the epitopes recognized can be defined with short synthetic peptides *in vitro*[6]. Haemagglutinin (HA), the major transmembrane protein of the virus, is recognized by a minor population of CTL from infected mice. We have deleted the sequence coding for the N-terminal signal peptide from a complementary DNA encoding HA of the H1 subtype. The signal-deleted HA is detected with antibodies as a short-lived, unglycosylated, intracellular protein. However, CTL raised to the complete molecule recognize cells expressing the signal-deleted HA and vice versa. These results cast doubts on the assumption that CTL recognize the HA molecule only after its insertion into the plasma membrane.

Intuitively, proteins that are naturally inserted into the plasma membrane should not require a special mechanism for recognition by CTL. The requirement for a hydrophobic signal peptide at the N-terminus of the HA molecule for its translocation into the lumen of the endoplasmic reticulum, insertion into the membrane, glycosylation and transport to the cell surface[7,8] formed the basis for our experiment. If CTL recognize haemagglutinin only after it has been inserted into the plasma membrane then cells expressing signal-deleted HA should not be recognized by HA-specific CTL. If an independent mechanism exists for presentation of HA in an appropriate form at the cell surface, then deletion of the signal sequence should not affect recognition by CTL.

The DNA encoding the HA signal sequence was deleted by oligonucleotide-mediated mutagenesis from a full-length DNA copy of RNA segment 4 from influenza A/PR/8/34 (H1 subtype, Mount Sinai strain, see ref. 2) as described[9] (Fig. 1*a*). We chose to express the signal-deleted HA from the 7.5K early promoter in recombinant vaccinia[10]. Such HA-vaccinia can prime mice efficiently for a haemagglutinin-specific CTL response[11,12], and express high levels of HA protein in cell lines *in vitro*. The recombinant viruses here are referred to as L$^-$H1-VAC (expressing the signal-deleted HA of the H1 subtype), H3-VAC (expressing the full-length HA of the H3 subtype from A/NT/60/68 virus) and H1-VAC (expressing the full length H1 haemagglutinin from the same promoter).

Fig. 1 *a*, Deletion of the H1 haemagglutinin (HA) signal sequence. *b*, Immunoprecipitation of signal deleted haemagglutinin. *a*, The N-terminal sequence of the H1 HA is from Winter *et al.*[13]. Sequence of the mutagenic oligonucleotide (24 bases) is underlined and the deleted segment coding for amino acids 2–17 is boxed. Mutagenesis was performed as described[9]. The mutant cDNA was sequenced by primer extension. The signal deleted H1 mutant and the full length H3 cDNAs were cloned into the vaccinia expression plasmid pGS62. Insertion into the vaccinia *tk* gene, isolation and purification of recombinant viruses followed standard procedures[10]. *b*, Murine L cells at 5×10^6 per ml were infected with 5–10 plaque forming units (PFU) of recombinant vaccinia virus per cell in RPMI containing 10% fetal calf serum (FCS) (RPMI/10) for 1.5 h at 37 °C. The cells were then washed twice in phosphate-buffered saline (PBS) and resuspended at 10^6 per ml in RPMI/5 for 3 h, washed twice in PBS and resuspended at 5×10^6 per ml in methionine-free RPMI, 5% FCS for 1 h before adding 120 μCi of ^{35}S-methionine for 30 min. They were then diluted to 10^6 cells per ml in RPMI/10 containing 4 mmol l^{-1} unlabelled L-methionine and the first aliquot of cells removed for lysis (time 0). The remainder were incubated at 37 °C and subsequent aliquots removed after 1 and 4 h. Immunoprecipitation was performed as described[5] on aliquots of 2×10^6 cells infected with L$^-$H1-VAC and NP-VAC (expressing the A/PR/8/34 nucleoprotein, used here as a specificity control), and 7×10^5 cells infected with H1-VAC. Reduced immunoprecipitates were electrophoresed on a 10% SDS polyacrylamide gel which was then treated with Amplify (Amersham), dried and exposed to pre-flashed X-ray film for 8 days. Lanes A–C, NP-VAC-infected cells immunoprecipitated with monoclonal antibody 469/6 (directed against nucleoprotein) at 0.1 and 4 h respectively after pulse labelling with ^{35}S-methionine. Lanes D–F, L$^-$H1-VAC-infected cells immunoprecipitated with H36-18-2 (anti-H1 haemagglutinin), time points as for A–C. Lanes G–I, H1-VAC-infected cells immunoprecipitated with H36-18-2, time points as for A–C.

The mutant gene, lacking the codons for amino acids 2–17 inclusive, should code for an unglycosylated protein of relative molecular mass 61.6K[13]. Figure 1*b* shows the results of a pulse-chase immunoprecipitation experiment using monoclonal antibody H36-18-2 that binds both the signal-deleted and full-length haemagglutinin. Immediately after a 30 minute pulse with ^{35}S-methionine, the mutant HA is weakly detectable in infected L cells at the expected position for unglycosylated HA (~60K, lane D). The full-length molecule migrates at about 68K, consistent with rapid core glycosylation (lane G). During the four hour chase period the mutant HA becomes undetectable, imply-

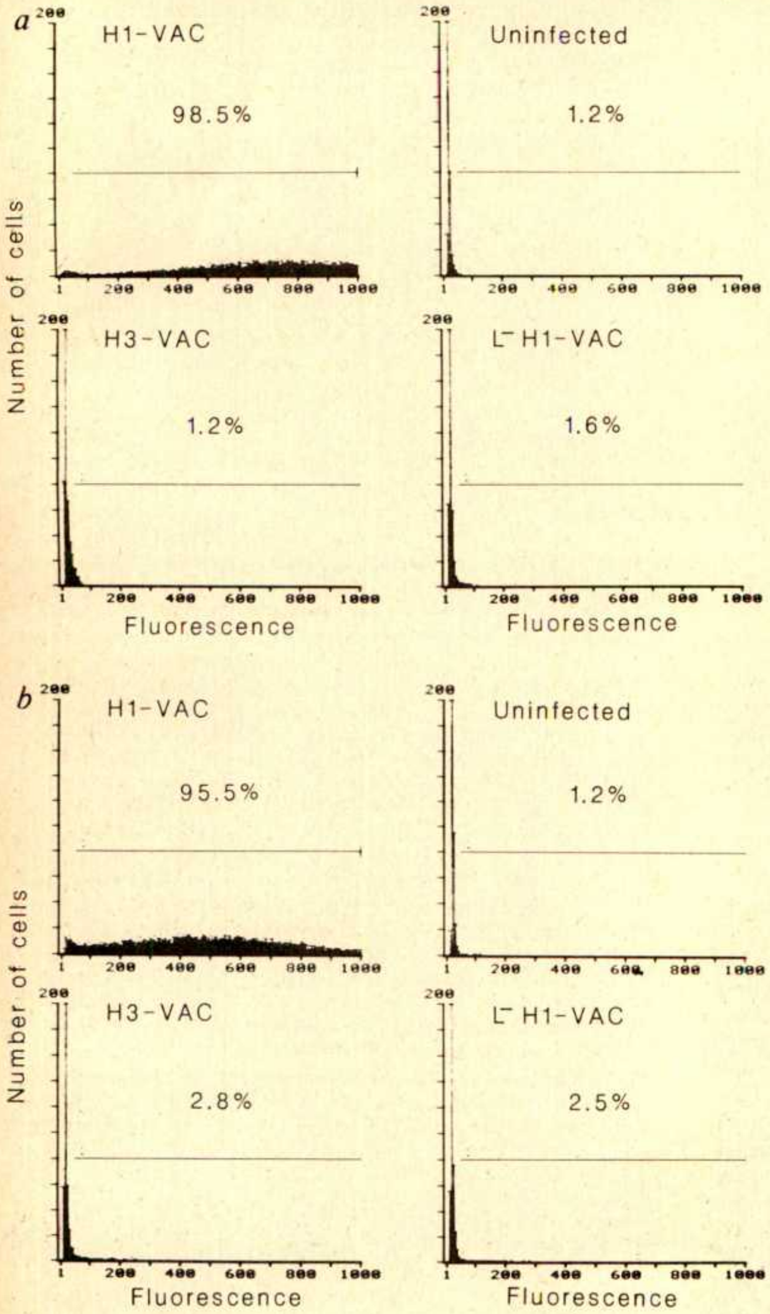

Fig. 2 Indirect immunofluorescence staining of L⁻H1-VAC- and H1-VAC-infected L cells. L cells were infected as described in Fig. 1 with either L⁻H1-VAC, H1-VAC, H3-VAC (included as a specificity control) or left uninfected. After 1.5 h cells were washed twice and resuspended at 10^6 per ml in RPMI/10 for 3 h at 37 °C. Aliquots of 5×10^5 cells were then stained by indirect immunofluorescence as described[5]. *a*, The first layer was H36-18-2 monoclonal antibody to H1 haemagglutin at 5 μg ml^{-1} after purification on protein A-Sepharose. The second layer was FITC-labelled affinity-purified goat anti-mouse antibody (Sigma) at 1:40 dilution. *b*, The first layer was hyperimmune rabbit anti-serum R401 raised to A/PR/8/34 virus diluted 1:2,000. The second layer was FITC-labelled affinity-purified goat anti-rabbit anti-serum (Sigma) diluted 1:100. The samples were analysed on an Ortho Cytofluorograf.

ing that it may be rapidly degraded (lanes D, E and F). In contrast the bulk of the full-length molecule progresses to a higher molecular mass of ~75K (lanes G, H and I). Control immunoprecipitations on cells infected with recombinant vaccinia expressing nucleoprotein (lanes A, B and C) gave a prominant band migrating at ~57K, as expected.

Figure 2 shows that the signal-deleted HA was not detectable at the cell surface with specific monoclonal (Fig. 2*a*) or polyclonal (Fig. 2*b*) antibodies. In contrast the full-length molecule was expressed at the surface of 98% of H1-VAC infected cells. In these experiments the target cells were infected for four and a half hours with recombinant vaccinia virus before being stained by indirect immunofluorescence. This is the equivalent of the mid time point in the ^{51}Cr release assay used to assess CTL recognition.

Recombinant vaccinia expressing the mutant and wild type HAs were then compared for their ability to prime CBA mice for a specific CTL response to the H1 subtype of influenza haemagglutinin. Animals primed *in vivo* with the L⁻H1-VAC were able to respond to wild-type HA expressed by A/PR/8/34 influenza virus *in vitro* as efficiently as mice primed with vaccinia expressing the full length HA. The response was shown to be specific because target cells expressing H1 but not H3 haemagglutinin were recognized (Fig. 3). Animals primed with H3-VAC (data not shown) did not make a detectable H1 haemagglutinin specific CTL response.

Finally, CTL from animals primed *in vivo* with A/PR/8/34 influenza virus were tested for their ability to recognize target cells expressing the signal-deleted HA. Most of the CTL in these polyclonal cultures are specific for conserved internal viral components that are shared by X31 (H3) and A/PR/8/34 (H1) influenza viruses. The subpopulation capable of recognizing haemagglutinin can be detected selectively with target cells expressing HA in the absence of other influenza proteins, after transfection or infection with a recombinant vaccinia[1,2,4,11,12].

Figure 4 (left panel) shows that the HA-specific CTL recognized target cells expressing the signal-deleted HA as efficiently as cells expressing the full-length molecule, despite the fact that

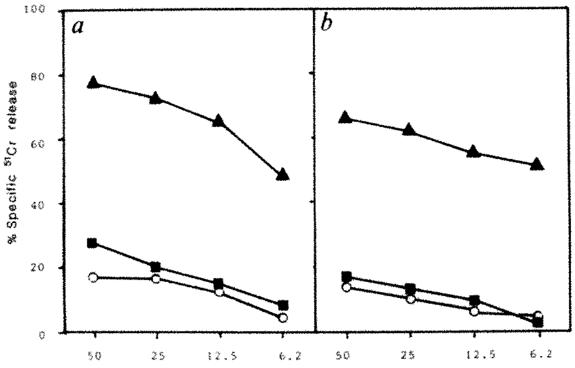

Fig. 3 The CTL response to infection by L⁻H1-VAC (*a*) and H1-VAC (*b*). Female CBA mice (obtained from NIMR Mill Hill), 3-6 months old, were primed intravenously by injecting 1×10^7 PFU of either L⁻H1-VAC or H1-VAC in 0.1 ml PBS into the tail vein as described[11]. After 12-14 days they were killed and their spleen cells stimulated *in vitro* with A/PR/8/34 influenza virus. After 5 days the responding cells were collected and tested by ^{51}Cr release assay on influenza-virus-infected L cells as described[1,2]. Responding CTL were incubated at the killer to target ratios indicated with ^{51}Cr-labelled target cells. Per cent specific ^{51}Cr release was calculated by (release by CTL − release in medium)/(2.5% Triton X-100 release − release in medium) × 100. Spontaneous release in medium from labelled L cells was 8-16% that released by Triton X-100. Target L cells were infected with; ▲, A/PR/8/34 (H1 subtype haemagglutinin); ■, A/NT/60/68 (H3 subtype haemagglutinin); ○, uninfected.

the appropriate antibodies could not detect HA on the surface of L⁻H1-VAC infected cells. Target cells infected with L⁻H1-VAC were not killed by a nucleoprotein specific T-cell clone, showing that recognition of the mutant HA was antigen specific. These experiments detect only CTL restricted through class I molecules of the major histocompatibility complex as the L cells used as targets do not express class II molecules.

These results are related to previous findings with nucleoprotein[5,6]. They show that CTL recognition of the haemagglutinin molecule (a typical glycosylated integral membrane protein[14]) does not depend on the presence of its signal sequence. Our findings suggest that an alternative route exists for the expression of HA at the surface of the cell in a form that is recognized by CTL. The lack of antibody binding to the L⁻H1-VAC-infected cell surface implies that the molecules recognized by CTL have disrupted tertiary structure. The pulse-chase experiment (Fig. 1) is consistent with this resulting from degradation of the mutant HA within four hours of its synthesis.

This conclusion is consistent with other recent published work. Wabuke-Bunoti *et al.* have shown that some HA-specific CTL can be induced *in vitro* with short synthetic peptides corresponding to regions of the H2 subtype haemagglutinin sequence[15]. Similarly, Yamada *et al.*[16] have described a recombinant protein produced in *Escherichia coli* consisting of the N-terminal 81 amino acids of the NS-1 protein fused to the C-terminal 210 amino acids of H1 haemagglutinin that was able to sensitize target cells for lysis by HA-specific CTL. We suggest, by analogy with the effect of denaturation on the recognition of proteins by T helper cells[17,18], that the tertiary structure of the HA fusion protein was disrupted enough to allow CTL recognition to occur.

Finally, Morrison *et al.*[19] have described Class I-restricted CTL that selectively recognized target cells in which new HA protein synthesis had occurred. In contrast their Class II-restricted CTL only recognized target cells that had been exposed to soluble HA in the surrounding medium. Our results argue that these findings can not be explained simply by the requirement for Class I-restricted CTL to recognize native HA inserted in the plasma membrane. We suggest that two pathways for presenting antigens to T cells exist, one dealing with proteins recently synthesized in the cytoplasm of an infected cell, the other concerned with endocytosed soluble proteins.

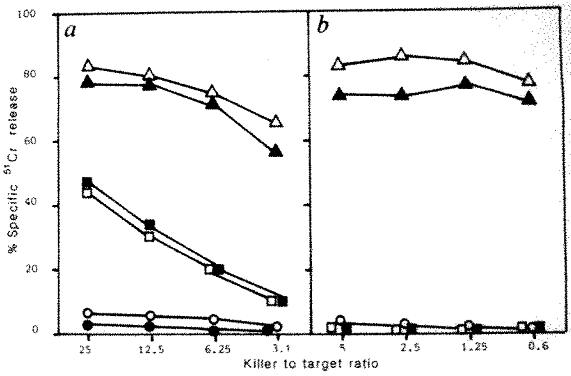

Fig. 4 CTL primed by full-length haemagglutinin recognize target cells expressing the signal-deleted molecule. *a*, Female CBA mice (3-6 months old) were primed intravenously with 100 haemagglutinin units of live A/PR/8/34 influenza virus. After 11 days spleen cells from primed animals were stimulated *in vitro* with A/PR/8/34 and collected for testing in the ^{51}Cr release assay as described in Fig. 3. Target cells used in this assay were L cells transfected with the Class I gene D^b (ref. 2). These cells were chosen so that the D^b-restricted nucleoprotein-specific CTL clone 11 could be used as an antigen specificity control. *b*, CTL clone 11 was isolated from a C57BL/10 mouse primed with influenza E61-13-H17 and restimulated with influenza X31 as described[20]. Clone 11 recognizes a conserved epitope on the nucleoprotein from human type A influenza viruses isolated since 1934 (J. Bastin, unpublished). Target cells were labelled with ^{51}Cr and infected with either recombinant vaccinia (5 PFU per cell) or influenza (200 μl of infectious allantoic fluid per 10^7 cells) for 1.5 h, washed twice, resuspended at 10^6 cells per ml in RPMI/10 for 3 h at 37 °C, washed twice and then used in the ^{51}Cr release assay as described[2]. Target cells were infected with; ■, H1-VAC; □, L⁻H1-VAC; ●, H3-VAC; ▲, A/PR/8/34 influenza (H1 haemagglutinin); △, X31 influenza (H3 haemagglutinin); ○, uninfected.

We thank G. Smith and B. Moss for the gifts of plasmid pGS62, recombinant vaccinia viruses H1-VAC and NP-VAC, and for initial help with vaccinia virus methodology. We are grateful to W. Gerhard, R. Webster and G. Schild for providing antibodies H36-18-2, 469/6 and R401 respectively; to N. Carter for analysing samples on the Ortho Cytofluorograf; to Claire Edmans for secretarial help and to the MRC for support.

H-2-restricted cytolytic T cells specific for HLA can recognize a synthetic HLA peptide

Janet L. Maryanski*, Pietro Pala*, Giampietro Corradin†, Bertrand R. Jordan‡ & Jean-Charles Cerottini*

It is generally accepted that T lymphocytes recognize antigens in the context of molecules encoded by genes in the major histocompatibility complex (MHC). MHC class II-restricted T cells usually recognize degraded or denatured rather than native forms of antigen on the surface of class II-bearing antigen presenting cells (reviewed in refs 1, 2). It has recently been shown[3] that short synthetic peptides corresponding to mapped antigenic sites of the influenza nucleoprotein (NP) can render uninfected target cells susceptible to lysis by NP-specific class I-restricted cytolytic T cells (CTL). These and earlier experiments[4] that showed specific recognition of NP deletion mutant transfectants suggest that class I-restricted recognition might also involve processed antigenic fragments. One important issue arising from these studies is whether the model applies not only to viral proteins that are expressed internally (such as NP) but also to antigens normally expressed as integral membrane proteins at the cell surface. We have recently isolated class I-restricted mouse CTL clones that recognize class I gene products of the human MHC (HLA) as antigens in mouse cell HLA-transfectants[5]. Here we show that these anti-HLA CTL can lyse HLA-negative syngeneic mouse cells in the presence of a synthetic HLA peptide. These results suggest that the model applies generally.

CTL clones were isolated as described elsewhere[5] from DBA/2 (H-2^d) mice immunized with syngeneic cells transfected with cloned HLA class I genes. A high efficiency transfection recipient[6] selected from mouse cell line P815 was used for DNA transfection. Anti-CW3 CTL clone 10.1 lysed P815 cells transfected with HLA-CW3, but not HLA-A3, -A24 or -B7 (ref. 5 and J.L.M., unpublished results). Recognition by this and other DBA/2 CTL clones directed against P815-HLA transfectants was shown to be restricted to H-2K^d (ref. 5). The antigenic determinant recognized by this CTL clone was mapped[7] to the second external (α_2) domain of HLA-CW3. Based on the amino-acid sequence of the α_2 domain of HLA-CW3 compared to the corresponding domain of HLA-A3, -A24 and -B7 and that of endogenous H-2^d class I molecules, we prepared a series of four synthetic peptides corresponding to 16-amino-acid segments of HLA-CW3 (Fig. 1).

Fig. 1 Comparison of the protein sequence of HLA-CW3[10], -A3[11], -A24[12], and -B7[13], and H-2K^d (ref. 14), -D^d (ref. 15), and L^d (ref. 16) from amino acid 83 to 188. Amino acid 181 of the HLA-CW3 sequence, erroneously given as G in ref. 10, has been corrected to R[17]. For H-2L^d, amino acids 121, 139 and 140 are given as C, S, and S, respectively in ref. 18. The four peptide sequences prepared synthetically are underlined.

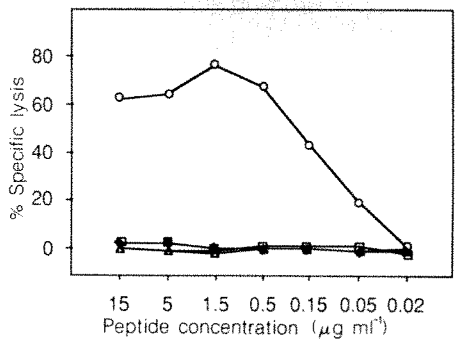

Fig. 2 Lysis of P815 target cells in the presence of peptide CW3(171-186) by anti-CW3 CTL clone 10.1. Synthetic peptides corresponding to HLA-CW3 amino acids 87-102 (△), 106-121 (◇), 151-166 (□) and 171-186 (○) were made according to the Merrifield method[19] as modified in ref. 20 using base-labile α-*N*-fluorenylmethoxycarbonyl protection. The peptides were cleaved from the resin with 90% aqueous trifluoroacetic acid, precipitated by addition of ether, redissolved in 10-20% acetic acid, chromatographed on a Sephadex G-25 column and eluted with 10-20% acetic acid. Peptides 87-102, 106-121 and 151-166 were then purified by reverse phase HPLC using a Permacoat C-6 column and elution with 0.1 M $NaClO_4$ in 0.1% H_3PO_4 buffer of *p*H 2 and a linear gradient of acetonitrile. Peptide 171-186 was purified by cation exchange HPLC using a Beckman Spherogel-TSK IEX 5.5 cm column and a linear gradient of NaCl in 0.01 M sodium phosphate buffer of *p*H 7.0. The peptides were lyophilized and dissolved in 0.7% sodium bicarbonate buffer. The HPLC-purified peptides gave the correct theoretical values of amino-acid composition and were >90% pure as judged by analytical HPLC. The purified peptides were diluted in Dulbecco's modified Eagle's medium (DMEM) containing 5% fetal bovine serum (FBS) and 100-μl volumes were added to wells of V-bottom microtitre plates. Cells (10^6) from P815-*tk*$^+$ clone 444/A1.1 (ref. 5) were labelled with 150 μCi sodium [^{51}Cr]chromate for 1 h at 37 °C and washed 3 times. Labelled P815 target cells (2×10^3 in 50-μl volumes) were added to wells containing peptides. 6×10^3 cells from anti-CW3 CTL clone 10.1 (ref. 5) in 50-μl volumes were then added to give an effector to target ratio of 3:1. After 4 h incubation at 37 °C the plates were centrifuged and 100 μl of supernatant was removed for counting. The % specific lysis was calculated as: (experimental − spontaneous release)/(total − spontaneous release) × 100. Spontaneous release in the absence of CTL or peptides was 14% of total counts. There was no effect on spontaneous release by any of the peptides. The specific lysis in the absence of peptides was 1%.

The CW3-specific CTL clone 10.1 lysed P815 cells incubated with peptide CW3 (171-186) very efficiently (Fig. 2). The minimum peptide concentration required for maximum lysis in this assay was 1.5 μg ml^{-1} (0.8 μM). The other three CW3 peptides tested were negative up to a concentration of 15 μg ml^{-1}. Another independently-derived H-2K^d-restricted DBA/2 anti-CW3 CTL clone (P1.1) apparently recognized the same HLA-

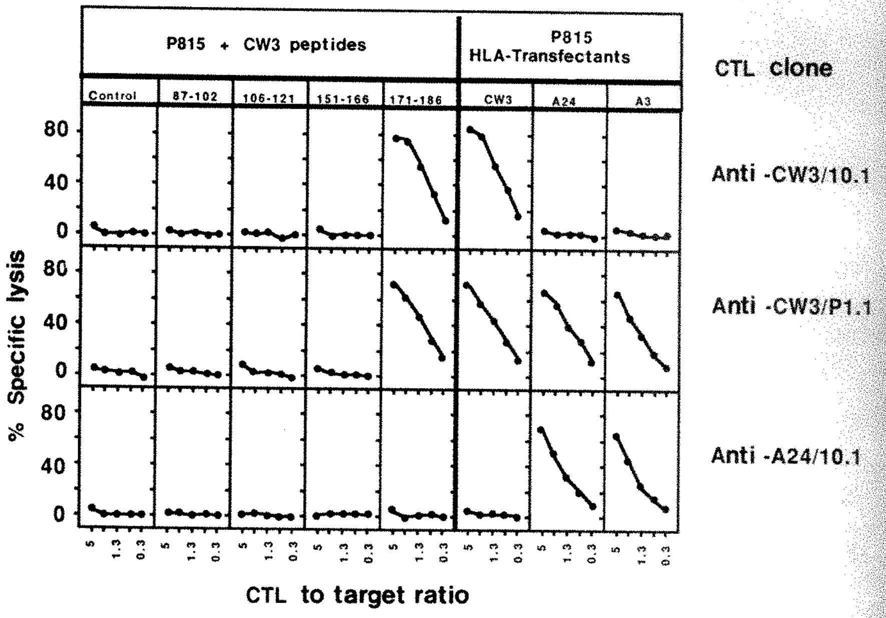

Fig. 3 Specificity of HLA-CW3 peptide recognition. Peptides CW3(171-186) and CW3(87-102) (100 μl at 10 μg ml^{-1} in medium containing 5% FBS) were added to conical microtitre wells. Cells (10^6) from P815 clones[5] transfected with the thymidine kinase (*tk*) gene only (clone 444/A1.1), with *tk* and HLA-CW3 genes (444/C9.3), with *tk* and HLA-A24 genes (452/D1), or with *tk* and HLA-A3 genes (504/2.1.4) were labelled with 150 μCi sodium [^{51}Cr]chromate for 1 h at 37 °C and washed 3 times. Labelled target cells (2×10^3 in 50-μl volumes) were added to wells that contained medium or peptides. Anti-CW3 CTL clones 10.1 and P1.1 were derived in independent experiments from DBA/2 mice immunized with P815 HLA-CW3 transfectant clone 444/C9.3, and anti-A24 CTL clone 10.1 was derived from DBA/2 mice immunized with P815 HLA-A24 transfectant cells[5]. Serial twofold dilutions of CTL in 50-4μl volumes were added to give the indicated CTL to target ratios and a final peptide concentration of 5 μg ml^{-1}. After 4 h at 37 °C the plates were centrifuged and 100 μl supernatant was removed for counting. Specific lysis was calculated as in Fig. 2.

CW3 synthetic peptide as clone 10.1 (Fig. 3). The fine specificity of the two CTL clones was not exactly identical, however. Clone P1.1 lysed P815-A24 and -A3 targets in addition to CW3 targets, unlike clone 10.1 that lysed only CW3 targets (Fig. 3 and ref. 5). Neither lysed HLA-negative P815-*tk*$^+$ cells. A third H-2K^d-restricted DBA/2 anti-HLA CTL clone that lysed HLA-A24 and -A3, but not -CW3 transfectants failed to react with any of the HLA-CW3 peptides, at concentrations of up to 30 μg ml^{-1} (Fig. 3 and J.L.M., unpublished results). Thus peptide recognition by these CTL clones (as measured by cytolytic activity) is specific, and antigenic sites for two different anti-CW3 CTL clones may be located within the same 16-amino-acid sequence.

These results clearly agree with those in ref. 3 showing specific cytolytic activity of anti-NP CTL in the presence of synthetic NP peptides. The reconstitution of specific target cell recognition with synthetic peptides strongly supports the hypothesis that class I-restricted T cells, like those restricted to class II antigens, recognize degraded or denatured antigenic fragments rather than intact antigen. It is noteworthy that HLA antigens, unlike the influenza NP, are integral cell membrane glycoproteins that can be easily detected on the cell surface with specific antibody[5,8]. Our results suggest, therefore, that recognition of antigenic fragments by class I-restricted T cells may be a general feature not limited to antigens that are virus-encoded and/or expressed primarily intracellularly.

Previous studies have shown that HLA class I gene products expressed in P815 mouse cells are involved in at least three categories of T-cell recognition. These include alloantigens recognized by alloreactive human CTL[8], HLA class I restriction elements recognized by human anti-viral CTL[9], and nominal antigens recognized by class I-restricted mouse CTL[5]. We have shown in this paper that the nominal HLA-CW3 antigen for two different class I-restricted CTL clones can be defined by a synthetic 16-amino-acid peptide. We have previously observed that lysis of P815-HLA transfectants by alloreactive human CTL but not by class I-restricted mouse anti-HLA CTL can be blocked by anti-HLA antibodies[5,8]. Together the results suggest that these human and mouse CTL recognize different forms of HLA that are presumably encoded by the same gene. It is possible that a membrane bound form of HLA in P815 HLA transfectants is recognized by alloreactive and by HLA-restricted antiviral human CTL, whereas a processed fragment of HLA is recognized as a nominal antigen by class I-restricted mouse CTL. The native and degraded forms of antigen may coexist on the cell surface. We believe P815-HLA transfectants will constitute an ideal system to investigate the nature of antigen complexes recognized by T cells.

We thank K. Mühlethaler and C. Vonnez for expert technical assistance and Dr H. R. MacDonald for helpful comments.

λ5, a new light-chain-related locus selectively expressed in pre-B lymphocytes

Nobuo Sakaguchi & Fritz Melchers

Basel Institute for Immunology, Grenzacherstrasse 487, Postfach,
CH-4005 Basel, Switzerland

The development from stem cells to pre-B cells, B lymphocytes and, finally, plasma cells and memory cells proceeds through various stages which have been defined by the genomic context in which immunoglobulin (Ig) heavy (H) and light (L) chain gene segments are found, as well as by their state of expression[1-7]. They have also been identified by surface marker analysis[5,8,9] and susceptibility to various stimuli regulating growth and differentiation[10]. We have searched for genes that are expressed at given stages in the B-lymphocyte development pathway and which might function to control this development at various stages. A com-

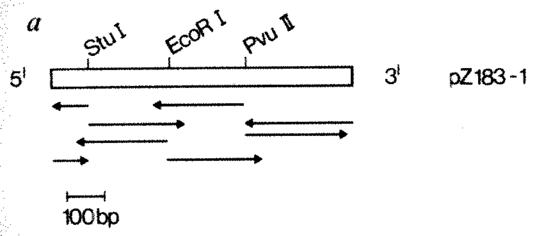

Fig. 1 Strategy for the sequencing and nucleotide sequence of the cDNA clone pZ183-1. The pZ183 cDNA clone was obtained as described elsewhere[11]. ^{32}P-labelled insert DNA was used to screen a pUC-13 cDNA library constructed from total poly(A)$^+$ RNA of 70Z/3 cells by the tailing method[25]. The restriction enzyme sites and the sequences are shown in *a*. The arrows indicate the direction and length of sequence determined by subcloning fragments into M13 phage vector and sequencing by the dideoxy-chain termination method[26]. The nucleotide sequence of the cDNA clone pZ183-1 is shown in *b*. The 5' to 3' orientation was deduced from the location of the poly(A) tail and the poly(A) attachment site (underlined). Nucleotide positions are numbered from the most 5' position of the insert cDNA fragment.

plementary DNA sequence called pZ183 was found in a library constructed from messenger RNA of the murine pre-B lymphoma cell line 70Z/3 which is selectively expressed in pre-B cells[11]. Here we report the nucleotide sequence of a cDNA clone (pZ183-1) containing 0.7 kilobases (kb) of the pZ183 gene. Part of this sequence shows strong homology to constant (*C*) and joining (*J*) region sequences of λ_1 L chains. Our findings define a new immunoglobulin L-chain-related locus, which we call λ5, that is selectively transcribed in pre-B lymphocytes.

During the somatic development of lymphocytes from precursor cells, gene segments in immunoglobulin gene loci are rearranged to form a complete variable (*V*) region exon which results in the translation into full immunoglobulin chains containing V- and C-region domains[12,13]. In the B-cell lineage rearrangement of heavy-chain diversity (D_H) segments to J_H segments precedes that of V_H to D_HJ_H segments[3,14,15]. V_κ is then rearranged to J_κ (refs 2, 16, 17) and, finally, V_λ to J_λ (ref. 18). The different steps of H, κ L and λ L rearrangments define different cellular stages of pre-B-cell development.

In our search for genes that are expressed at a given stage of pre-B-cell development, we had constructed a cDNA library from mRNA of (uninduced) 70Z/3 which was subtracted by a pool of mRNA molecules from a T-cell hybridoma[11]. We cloned the pZ183 cDNA which we found expressed selectively in pre-B cells at low to medium abundance[11]. It was present in 1 of 5,000 in the unsubtracted library and in 1 of 350 cDNA clones in a subtracted library from the same source of poly(A)$^+$ RNA of 70Z/3. Mature B cells, plasma cells, T cells, macrophages and a variety of cells from other lineages and tissues did not express detectable levels of the corresponding gene.

The cDNA clone with the longest (0.7 kb) insert, called pZ183-1, was obtained from a cDNA library constructed in the pUC-13 vector from a poly(A)$^+$ mRNA of uninduced 70Z/3 and sequenced as outlined in Fig. 1*a*. The nucleotide sequence is shown in Fig. 1*b*. Next to the poly(A) tail lies a poly(A) attachment site which orients the pZ183-1 sequence from 5' to 3'. The three longest open reading frames deduced from the cDNA sequence were considered as possible candidates for the polypeptide sequence: the longest frame between bases 1 and 553 (184 residues), the second between bases 9 and 281 (93 residues) and the third between bases 183 and 462 (93 residues).

We then searched a DNA sequence data bank[19] for possible evolutionary relationships of the pZ183-1 sequence to known DNA sequences. Strong homology was detected for positions

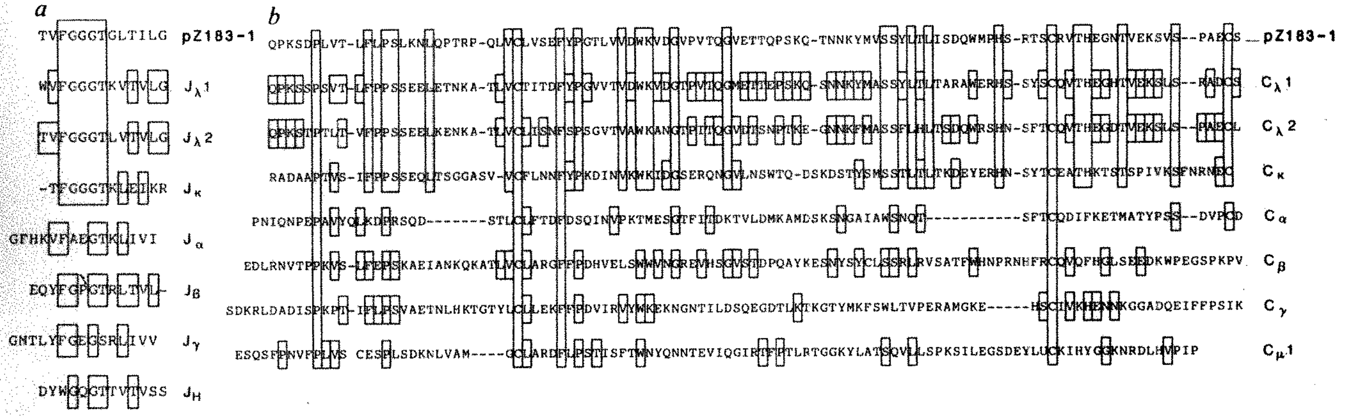

Fig. 2 Possible amino acid sequence of the *J*-like (*a*) and *C*-like (*b*) portions of pZ183-1 deduced from the nucleotide sequence in Fig. 1*b* in frame 1 and alignment with the corresponding sequences of λ1 L (refs 21, 27), λ2 L (refs 21, 27), κ L (ref. 21), J_H and $C_\mu 1$ (ref. 21) and J_α $C_\alpha 1$, J_β C_β and J_γ C_γ of the α, β and γ chains of the T-cell receptor[22,24,28]. See Table 1 for nucleotide positions corresponding to first and last deduced amino acid of the *J*-like and *C*-like sequences of pZ183-1. Those residues common between pZ183-1 and any other sequence are boxed. Residues conserved in all sequences or conserved in light chains are boxed together.

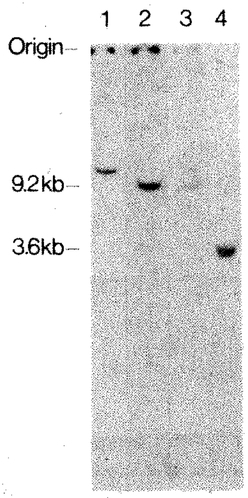

Fig. 3 Southern blot analyses of DNA from 70Z/3 cells. DNA was digested with the restriction enzyme *Hin*dIII, electrophoresed through a 1.0% agarose gel, blotted onto nitrocellulose filters and hybridized with the ^{32}P-labelled insert of the clone pZ183-1 (lane 1). Hybridization was carried out at 42 °C in 50% formamide and 5 × SSC. The filters were washed at 65 °C in 0.2 × SSC. After exposure to X-ray film, the same filter was washed in H_2O 0.1% SDS at 95 °C for 10 min and used repeatedly to probe successively with $C_\lambda 1$ [*Xho*I-*Pst*I fragment of pAB1-1 (ref. 27) (lane 2), both pZ183-1 and $C_\lambda 1$ (lane 3)] and $C_\lambda 2$ (450-bp *Sac* I fragment[23] (lane 4).

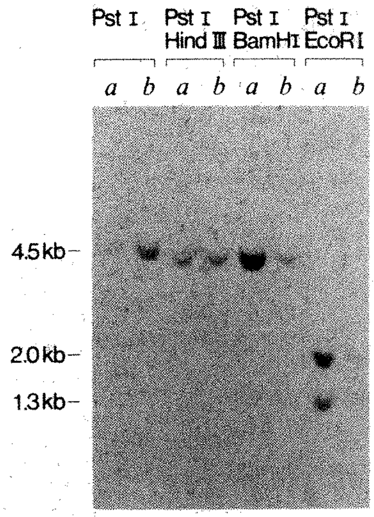

Fig. 4 Southern blot analyses of DNA from liver of (C57BL/6J × DBA/2)F_1 mice (*a*) and from 70Z/3 pre-B cells (*b*). DNA was digested with the indicated enzymes. The filter was hybridized with ^{32}P-labelled insert DNA of cDNA clone pZ183-1 under conditions described in Fig. 3 legend.

240–554 to the *C*-region nucleotide sequence of λ1 L chains. Equally strong homology was found for the adjacent 5′ positions 201–239 to the *J* segment sequence of λ1 (Table 1). The reading frame of the λ1 L-chain *J* + *C* nucleotide sequence was then imposed on the pZ183-1 sequence as a reading frame. This was found to be reading frame 1 (starting with nucleotide 1) of the sequence shown in Fig. 1*b*. Comparison with the λ1 nucleotide sequence shows that the first stop codon in frame 1 of the pZ183-1 sequence occurs at the same position as the first (functional) stop codon of λ1 L chains. Reading frame 1 is therefore the most likely candidate for a translatable sequence.

The amino acid sequence encoded by the *J*- and *C*-like regions of the pZ183-1 gene deduced from reading frame 1 is shown in Fig. 2 and compared with corresponding sequences of immunoglobulin and T-cell receptor proteins. Again, the strongest homology is detected with the *J* segment and *C* domain of λ1 L chains (Table 1).

Table 1 Homologies of pZ183-1 sequences with immunoglobulin light-chain genes and proteins

Sequence position of pZ183-1	L chain	Ref.	Homology with nucleotide sequence (%)*	Homology with deduced amino acid sequence (%)†
240–554	$C_\lambda 1$	21, 22	77.9	66.7
	$C_\lambda 2$	21, 22	70.2	61.1
	$C_\lambda 3$	22, 23	70.9	61.1
	$C_\lambda 4$	23	73.5	—
	C_κ	22, 24	22.5	30.8
201–239	$J_\lambda 1$	21, 22	67.5	66.0
	$J_\lambda 2$	21, 22	70.2	75.0
	$J_\lambda 3$	22, 23	67.6	50.0
	$J_\lambda 4$	23	70.2	—
	$J_1\kappa$	22,24	59.4	58.0

* Nucleotide sequence comparisons were done by a computer program and are shown as per cent matches per length.

† Alignment of the deduced amino acid sequence of pZ183-1 with mouse λ1, λ2, λ3 and λ4 L chains, as well as with κ L chains was done to maximize identities and structural homologies with pZ183-1, paying special attention to the alignment of certain key conserved residues.

Furthermore, pZ183-1 shows cysteine residues at the consensus positions characteristic of all immunoglobulin domains, and has the consensus sequence WVFGGGTKVTVLG characteristically encoded by *J* segments of the immunoglobulin genes. These results suggest that the 3′ portion of the pZ183-1 cDNA clone belongs to a λ L-chain-related gene locus which we call λ5 ($J_\lambda 5$, $C_\lambda 5$).

In contrast, the 5′ sequence adjacent to the $J_\lambda 1$-like sequence of pZ183-1 shows no strong homology to $V_\lambda 1$, any other known *V* segment or any other gene known to us. It does not contain a cysteine at the position where a consensus cysteine residue would be expected in V-region domains of immunoglobulins. The 5′ sequence adjacent to the *J*-like sequence of pZ183-1 also reveals no homologies to intron nucleotide sequences either 5′ of $J_\lambda 1$ or 3′ of $V_\lambda 1$. The segment cDNA clone is apparently too short to contain an initiation codon. We therefore cannot rule out the possibility that the pZ183-1 cDNA is derived from a sterile transcript.

The gene is carried in the genome of 70Z/3 cells in a *Hin*dIII fragment of >9.2 kb (Fig. 3, lane 1). Southern blot analysis shows that it is different in context from $C_\lambda 1$ (Fig. 3, lane 2) and $C_\lambda 2$ (lane 4). The unknown 5′ sequences and the $J_\lambda 1$- and $C_\lambda 1$-like 3′ sequences of pZ183-1 appear to be on the 4.5-kb *Pst*I fragment. The gene is on one *Pst*I/*Bam*HI and one *Pst*I/*Hin*dIII genomic fragment, each 4.2 kb long. Double digestion with *Pst*I and *Eco*RI yields two fragments of 1.3 and 2.0 kb (Fig. 4). No differences in the lengths of restriction enzyme fragments of DNA from liver and from 70Z/3 cells have been detected (Fig. 4). This indicates that the 5′ and 3′ regions of the pZ183-1 gene are near each other, that is, on one 4.3-kb fragment in germline DNA. We have therefore not found any sign that they are rearranged during pre-B-cell development. This also makes it unlikely that a chromosomal translocation or viral insertion occurred in close proximity to the pZ183-1 sequences in either the chemically induced 70Z/3 pre-B cell or the Abelson virus-induced pre-B-cell lines in which the same gene is expressed with the same size transcript of 1.2 kb[11].

The size of pZ183-1 transcripts, 1.2 kb, predicts a protein of similar size to L chains. With its penultimate cysteine at the carboxy-terminal end it could form homodimers (for example, L-chain dimers) or heterodimers. H chains could be partners in this heterodimer formation as soon as they are expressed in pre-B cells, and this may allow H chains to appear on the surface of pre-B cells, as previous experiments have indicated[9]. Such a surface deposition of the expressed H chains would significantly alter our present view of the development of the B-cell repertoire.

It had previously appeared that all the loci in mouse which encode antigen-binding immunoglobulin molecules of B lymphocytes had been identified, although considerable changes in the complexity of λ1 L-chain loci has been observed in wild mice[28]. However, our results suggest that immunoglobulin-related genes may exist which function only at an early stage in ontogeny and which so far have gone undetected.

We thank Ms Heidi Bächtold and Denise Richterich for technical assistance and Dr Klaus Karjalainen for critical reading of our manuscript. The Basel Institute for Immunology was founded and is supported by F. Hoffmann-La Roche & Co., Basel, Switzerland.

Long-range restriction map around the Duchenne muscular dystrophy gene

Margit Burmeister & Hans Lehrach

EMBL, Postfach 102209, Meyerhofstrasse, 6900 Heidelberg, FRG.

Duchenne muscular dystrophy (DMD, reviewed in ref. 1) is an X-linked recessive disease affecting about 1 in 4,000 newborn boys. As in many other inherited diseases, the biochemical basis of the condition is unkown, and as yet there is no effective treatment. Translocations, deletions and other mutations leading to the DMD phenotype are distributed over a chromosomal area of large, but unknown size[2,3]. Using pulsed-field gradient gel electrophoresis[4,5], we have now determined restriction maps of a major fraction of this area, covering two regions of three million basepairs in total, and used it to determine the position of several probes linked to DMD. The maps establish physical distances between structural changes associated with the DMD phenotype and provide evidence for a CpG-rich island proximal to the area containing translocations and deletions associated with the DMD phenotype.

Using either molecular or genetic mapping, translocations, deletions or other mutations causing the DMD phenotype have been found distributed over an unusually large area of the X chromosome[2,3]. Although more complex genetic arrangements are possible, the simplest explanation is a single, but very large gene responsible for DMD. Two probes closely linked to the DMD gene and probably contained within have been cloned using different approaches. Subclones of a 200-kilobase (kb) cluster cloned around probe pERT87(DX164)[6] are deleted in about 6.5% of all DMD patients[3], suggesting that parts of the DMD gene might be deleted. Probe pXJ1.1 (ref. 7) is also assumed to be at the DMD gene, since it is derived from the chromosomal breakpoint of an X-chromosomal translocation found in a female DMD patient. As in other female DMD patients[2], the disease is assumed to arise due to disruption of the DMD gene by the translocation. Although extensive chromosomal walking has been carried out around both probes (P. Ray and R. Worton, and A. Monaco and L. Kunkel, personal communications), the two cloned regions could not be joined.

In contrast to most other genes, the size of the region implicated in the DMD phenotype is therefore too large to be easily accessible to standard molecular techniques. Recently, however, a new method, pulsed-field gradient (PFG) gel electrophoresis[4,5], has been developed, allowing the analysis of DNA fragments of 50-1,500 kilobases (kb); this range is not covered either by molecular cloning or by classical genetic approaches. We therefore decided that the analysis of the DMD locus would be considerably facilitated by mapping the positions of cloned probes relative to each other. Since these probes are associated with structural changes leading to a DMD phenotype, the positions of mutations leading to DMD are determined and estimations of a minimal gene size are possible.

We have analysed five probes closely linked to and flanking the DMD gene using the PFG technique. In addition to probes pERT87 and pXJ1.1, which are very close to or at the DMD gene, the closest available polymorphic markers on the distal side, B24 (DXS67) and C7(DXS28)[8], about 5-15 cM from DMD[9], and L1-4 (DXS68)[10], a non-polymorphic marker localized between pERT87 and C7 (ref. 9), were included. Deletion analysis[9,11-13] indicates the probe order pXJ1.1/pERT87/L1-4/C7/B24, and maps the genes for glycerol kinase and adrenal hypoplasia between pERT87 and C7.

To establish a physical map in this region, DNA was cleaved with different restriction enzymes cutting rarely in the mammalian genome, separated on PFG gels, and transferred to nylon filters for analysis. Filters were hybridized successively with each of the five probes. Probes pERT87-30 (the most distal subclone of the pERT87-cluster) and pXJ1.1 detected common restriction fragments; B24 and C7 were similarly shown to be physically linked. To generate a restriction map, double digests with combinations of enzymes were performed and analysed (see Fig. 1). The results of this analysis are summarized in Table 1. In a manner analogous to conventional restriction mapping, the data were used to deduce restriction maps covering hundreds of kilobase pairs. The restriction maps constructed (see Fig. 2 and legend for details) show that probes pXJ1.1 and pERT87-30 are at least 100, but no more than 400 kb apart. This result also gives the distance between the X/21 DMD translocation[7] (of which pXJ1.1 is a junction fragment) and common DMD deletions (100 kb proximal of pERT87-30, around pERT87-8)[3] as maximally 300 kb (see Fig. 2). The size of the DMD gene is probably larger, however, since some mutations map distal to pERT87-8.

Overlapping clones which extend ∼200 kb proximal to pERT87-30 have been isolated without joining the segment cloned around pXJ1.1 (ref. 3 and A. Monaco and L. Kunkel, personal communication); thus the maximum additional walking distance between the two cloned segments is now no more than 200 kb, and more likely to be much less.

B24 and C7 are the closest published markers distally flanking the DMD gene[9]. They are also of particular interest, since deletions which produce a syndrome of adrenal hypoplasia, glycerol kinase deficiency and DMD, map proximal to these markers[11-13]. Our results show that these two probes lie within a distance of 250–700 kb from each other. We could not show physical linkage between these probes and the pERT87/pXJ1.1 cluster (Fig. 2, Table 1). In an attempt to detect physical linkage between the two clusters, probe L1-4, which had been localised between C7 and pERT87-30 by deletion analysis[9,11], was hybridized to the same filters. No common restriction fragments were

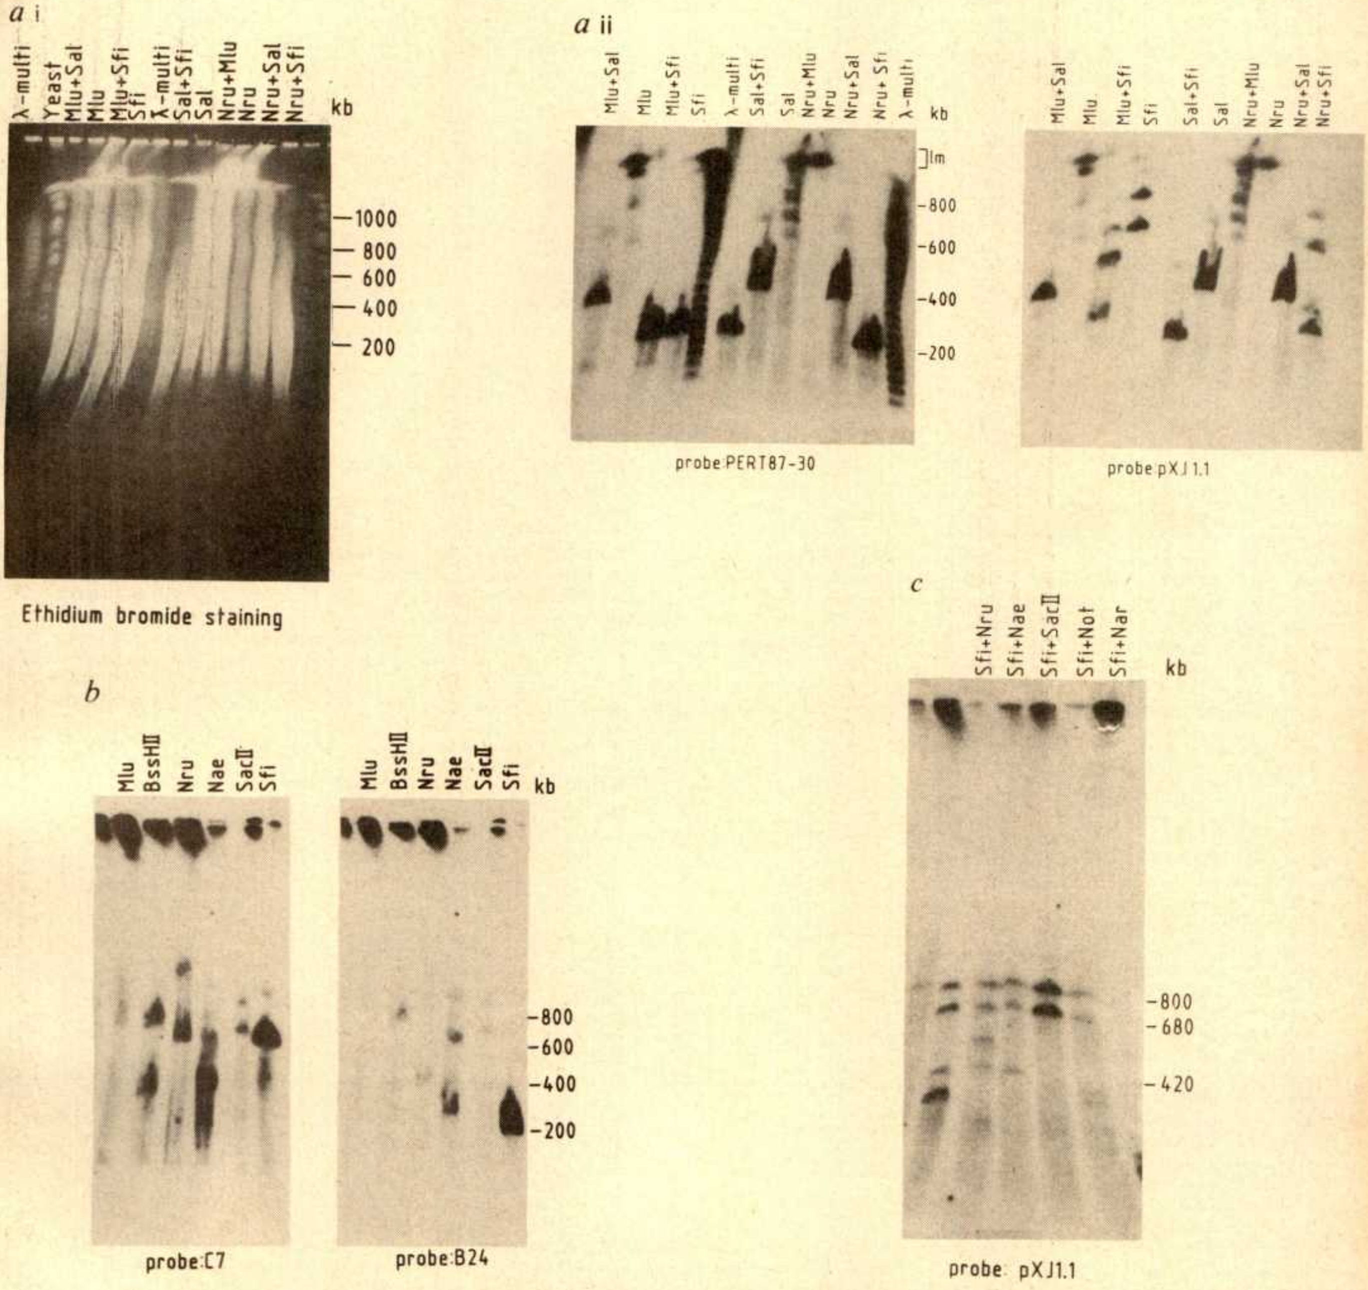

Fig. 1 Hybridizations to PFG gels. *a*, Linking probes pXJ1.1 and pERT87-30; *b*, common bands detected by probes B24 and C7; *c*, indications for an CpG-rich island near probe pXJ1.1. *a*, Ethidium bromide staining and autoradiograms of a gel run for 38 h at 15 °C with alternating switching of 48 to 90 seconds; These conditions give good resolution in the 200–600 kb range, but no resolution above about 900 kb. Size markers were both yeast chromosomes[4] and λ EMBL3 (ref. 18) polymers (λ-multi), which were generated by annealing the *cos* ends in agarose blocks. The unit size of EMBL3 is 43.2 kb. The autoradiograph at left shows the hybridization of λ DNA in addition to the probe used to visualize the size markers. The region of limiting mobility, lm, is the position of DNA fragments bigger than about 900 kb. *b*, This gel was run for 39 h at 9 °C with alternating switching times of 30 to 130 s, resolving also DNA fragments above 1,100 kb. Enzyme digests and probes are as indicated in the figure. Yeast chromosomes run on the same gel were used as size markers. c, Double digests of DNA with *Sfi*I and other enzymes as indicated were run on a PFG gel for 40 h at about 20 °C with alternating pulses of 30 and 130 s. *Sfi*I + *Not*I is equivalent to *Sfi*I alone. A common 390-kb fragment is detected with four enzymes in double digests with *Sfi*I. (*Sfi*I/*Bss*HII digests result in a similar fragment not shown in this figure). A 390-kb fragment is also observed when DNA is digested with *Nae*I alone. Therefore, the 390-kb fragment seen in the *Sfi*I + *Nae*I lane does not argue for the localization of an NaeI site close to the *Bss*HII/*Sac*II/*Nar*I/*Nru*I cluster.

Methods. Preparation of DNA for PFG was essentially as described[19]. Exact conditions for DNA preparation, running conditions and blotting will be published elsewhere[20]. A detailed protocol is available on request. The cell line LCL127 (48, XXXX, a gift from U. Francke, Yale) was used as a source for DNA in all cases. The source of the DNA is important because of observed methylation differences. Many sites seen in this cell line were not detectably cut in male blood cell DNA. Restriction enzymes were from New England Biolabs and were used as recommended by the manufacturer. Pulsed field gel electrophoresis[4] was carried out in a slightly modified box. The field was inhomogenous in both directions, the voltage gradient $10\ \mathrm{V\,cm^{-1}}$. Pulse times are as indicated above. After staining and photography, gels were alkaline-blotted onto Gene Screen nylon membranes. Inserts were isolated from low melting point agarose gels labelled by random oligo-priming[21] to a specific activity of around $1\text{-}4\times10^{9}$ d.p.m. μg^{-1} DNA. Hybridisations were carried out as described[22] for at least 24 h. Exposure was for 1 to 7 days at −70 °C with Kodac-X-Omat films preflashed once. Before reprobing, filters were stripped with 2 mM Tris/HCl *p*H 8, 0.1% sodium dodecyl sulfate at 80 °C. When the strongest band from the previous hybridization was not visible after reprobing, stripping was considered complete.

Table 1 Summary of hybridization results

Sizes of bands are in kilobase pairs. A dash indicates that no band was observed; ND, not determined. To confirm identity of bands recognized by two probes, several gels were run using different pulse times giving optimal resolution for different size ranges, minimizing the accidental comigration of non identical bands. For the construction of the map, we also considered the intensity of bands relative to the strong *Sfi*I-bands. Strong bands (>30% of the intensity of *Sfi*I, considered cut to completion) are underlined and very weak bands (<5% the intensity of *Sfi*I) are in brackets. Note that weak bands can arise from a site which is cut to completion, when the second site is incompletely cut. The partial bands produced by *Sfi*I as recognised by pXJ1.1 and L1-4 might reflect methylation in recognition sequences of the type GGCmCGNNNNNGGCC or GGCCNNNNNGGCmCG. In this case observation of two bands due to an RFLP can be excluded, since two bands are also observed in an *Sfi*I digest of DNA from male blood cells (not shown). *Nae*I, although often producing bands on pulsed-field gels, gave a rather complex pattern with four and more bands (see Fig. 1*b*). These could not be interpreted without ambiguities. *Nae*I-fragments recognized by probes were therefore not considered in the construction of the map, and are not listed here.

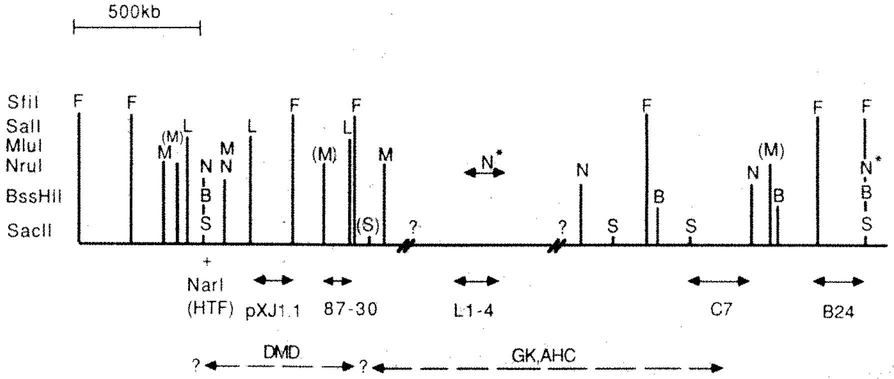

Fig. 2 Long range restriction map. The data for producing the map are summarized in Table 1. Weakly cut (highly methylated) sites are in brackets. The approximate locations of the DMD-gene(s) and of the glycerol kinase (GK) and congenital adrenal hypoplasia (AHC) genes are indicated below the map. Note that physical linkage of probes is only considered proven when at least three common bands generated by different enzymes were observed. Limits of localization for the probes used are indicated by arrows around the probe names below the map. In addition to the sizes of bands detected, the methylation status of a site was also considered for the construction of the map. The degree of methylation was estimated from the ratio of intensity of bands in double digests of enzymes cutting completely with the enzyme in question. Sizes were estimated with respect to yeast and λ size markers. It should be noted that the absolute sizes can only be considered to be approximate, because the amount of DNA loaded and pulse times[19] can slightly change the apparent size of a fragment. Comigration of two fragments was considered to be reliable, since the same blots were used for different probes. Since the cell line LCL127 is not homozygous for the X-chromosome, we can not rule out that some partial cutting is due to polymorphisms rather than methylation. Thus the map might have combined sites from two different chromosomes in a few instances. For the pERT87-30/pXJ1.1 cluster (Fig. 1*a*) subclones pERT87-30, localized about 50 kb distal of pERT87-15 (ref. 3 and Monaco and L. Kunkel, personal communication) and pXJ1.1 were used. Both pERT87-30 and pXJ1.1 recognize the same *Sal*I-fragment, but different *Sfi*I-fragments. Double digests of *Sfi*I and *Sal*I localize the *Sfi*I-site between the two probes approximately to the middle of the *Sal*I-fragment. Therefore, probe pXJ1.1 is located within 200 kb of the end of the large *Sfi*I fragment. Double digests with *Sfi*I/*Mlu*I and *Sfi*I/*Nru*I give the position of *Mlu*I and *Nru*I sites from the end of the *Sfi*I-fragment, similar to partial cosmid mapping[23]. A very weakly cutting (highly methylated) *Mlu*I-site within the *Sal*I fragment is detected in *Sal*I/*Mlu*I double digests. This *Mlu*I site cleaves the *Sal*I fragment into fragments of about 100 kb (hybridizing to pERT87-30) and of about 300 kb (hybridizing to pXJ1.1). The subclone pERT87-1, about 100 kb closer to pXJ1.1 than pERT87-30, recognizes the 300-kb *Sal*I-*Mlu*I fragment (not shown). This *Mlu*I-site is localized within the small *Sfi*I-fragment seen by pERT87-30, since it is also detected in a *Sfi*I/*Mlu*I digest by pERT87-30 as a weak *Sfi*I/*Mlu*I band of ~100 kb. Therefore the distance between pERT87-30 and pXJ1.1 is at least 100 kb, the distance between the weakly cut *Mlu*I site and the *Sfi*I-site separating the two probes. In the B24/C7 cluster (Fig. 1*b*), Probes B24 and C7 recognize the same *Sac*II fragments, but different *Sfi*I-fragments. A *Sac*II/*Sfi*I double digest then identifies a *Sac*II-site in the *Sfi*I-fragment of C7. The size of the common *Sac*II fragment predicts that the *Sfi*I fragments recognized by B24 and C7 are adjacent. There are different *Nru*I fragments recognized by these two probes. A *Nru*I/*Sfi*I double digest localizes one *Nru*I-site within the *Sfi*I-fragment seen by C7. Since the *Nru*I fragments are not shared, they point in opposite direction from this *Nru*I-site. This state of the map predicted a 250-kb *Nru*I/*Sac*II fragment recognized by C7, which could be confirmed (data not shown). Similarly, the *Bss*HII-sites were localized. Since *Nru*I does not cut the *Sfi*I-fragment seen by B24, the *Nru*I sites leading to a 450-kb *Nru*I fragment around B24 cannot be localized except for flanking the *Sfi*I fragment. A suggested *Nru*I-site (asterisk) is shown at the right hand side of the map. The additional *Nru*I-fragment of about 1,100 kb hybridizing to C7 seems not to be corecognized by B24, thus would be localized further to the left of the map (proximally). But as B24 hybridizes rather weakly, we can not completely rule out that the hybridization signal in this case was too weak to be detected. Therefore, the localization of the *Nru*I-site in the direction of L1-4 (asterisk) is considered not proven. The probe L1-4 could not link to any of the clusters (not shown). A 850-kb *Bss*HII fragment is recognized, and two *Sfi*I-fragments of 220 and 350 kb. As no bands are shared, the minimal distance between the *Mlu*I site distal of pERT87-30 and the *Nru*I site proximal to C7, is 500 kb, giving the distance of C7 to pERT87-30 as at least 1,000 kb.

recognized by L1-4 and any of the other probes. Taking the largest fragments not shared into account, the distance between the probes C7 and pERT87-30 must be at least 1,000 kb (Fig. 2).

When hybridizing pXJ1.1 to DNA restricted with *Sfi*I and several CpG-recognizing enzymes (*Nru*I, *Nar*I, *Sac*II and *Bss*HII) new fragments of identical size (390 kb) were detected in each case (see Fig. 1*c*). Since the probe pXJ1.1 is localized close to one end of the *Sfi*I fragment, these four sites must be localized, within the resolution of the gel, in close proximity to each other, 200-300 kb proximal to the probe pXJ1.1 (see map in Fig. 2). Such a clustering of sites would be expected in the case of an HTF (*Hpa*II tiny fragments) island[14,15], often found in close proximity to the 5′ end of genes. Very recently (data not shown) we found that at least some sites in the postulated HTF-island are cut to completion in DNA isolated from human sperm. The partial cutting of the sites observed here (Fig. 1*c*) is probably due to methylation of HTF-islands in inactivated X chromosomes[14]. Thus, with respect to methylation, this cluster behaves like known HTF-islands on the X-chromosome[14]. Since deletions in the pXJ1.1 region have a DMD phenotype as their only common effect[16,17], such an CpG-rich island could indicate the promoter sequence for the gene responsible for the DMD mutation. This would require the DMD gene to have a size of at least 600 kb (distance of the HTF island to the start point of the most distal published deletion[3]), with transcription proceeding in the direction centromere to telomere. Alternative models (for example, multiple clustered genes responsible for the same phenotype) can not be ruled out, but such a large gene size would be compatible with both the high incidence of DMD mutations and the observed distribution of deletions, translocations and other mutations associated with the disease throughout a very large chromosomal segment.

A complicating observation in the PFG analysis was partial cleavage of sites, resulting in multiple and weak bands recognized by these unique probes (compare, for example, the *Sfi*I-bands to all others in Fig. 1*a*, *b*). Partial restriction is caused by the sensitivity of all enzymes cutting rarely in the mammalian genome to CpG methylation in their recognition site. On the other hand, these partial digests added important information for mapping the region, since more sites can be analysed. Some of these sites might be due to polymorphisms since the lymphoblastoid cell line used contains four X chromosomes. This cell line was found to yield more visible bands than, for example male blood, as a result of a higher signal and/or hypomethylation. Nevertheless, major parts of the maps could be confirmed using DNA isolated from blood or sperm (not shown). All rare-cutting enzymes (except *Sfi*I, but see Fig. 1 legend) contain at least one, and usually two, CpG sequences in their recognition site. Reduced cleavage by CpG-recognizing enzymes is especially noticeable in the region surrounding the DMD locus, which appears to be depleted of unmethylated CpG-rich sites compared to other regions of the human genome which have been examined in our laboratory (M. Búcan *et al.*, unpublished data). For example, the enzyme *Not*I does not cleave within the entire region analysed. This obvious sparsity of unmethylated CpG-rich sequences might be correlated with a relatively low density of genes in this region, also indicated by the fact that large deletions around the DMD locus are associated with very few phenotypes[16,17]

We have described here partial physical maps covering ~3000 kb, about 2% of the human X chromosome. Such a map will be extremely useful in determining the exact size of the DMD gene(s), and will allow us to estimate the positions and extents of translocations and deletions in this area. The immediate positioning of new clones in the DMD area is now possible, with a resolution difficult to reach by purely genetic approaches.

We are especially grateful to Denise P. Barlow, who developed the PFG technology. We thank Anthony Monaco and Louis Kunkel, Peter Ray and Ron Worton, and Jean-Louis Mandel for providing the probes, Uta Francke for introducing us to the DMD problem, Marija Bucan for preparing some of the filters used, Gert-Jan van Ommen and Louis Kunkel for discussions, Denise P. Barlow, Michael Hortsch, Frank Michiels and Lisa Stubbs for critical reading of the manuscript, and Carol Stettner and other members of the electrical and mechanical workshops at the EMBL, for building the pulsed field gradient gel equipment.

Note added in proof: The recent publication of a cDNA from the DMD gene (A. M. Monaco *et al.*, *Nature* **323**, 646-650) confirms the direction of transcription and minimal gene size postulated here.

Immunoglobulin (Ig) variable (V) region genes are assembled in precursor B (pre-B) lymphocytes from multiple germline segments. The heavy-chain V-region gene is composed of variable (V_H), diversity (D) and joining (J_H) segments; kappa (κ) and lambda (λ) light-chain V-region genes have analogous V_L and J_L segments. Assembly of Ig V-gene segments, as well as those of the highly related T-cell receptor, is regulated at several levels and shows both stage and tissue specificity; for example Ig heavy-chain V-gene assembly precedes that of Ig light chains during B-cell differentiation[1]. Joining of all classes of V-gene segments involves conserved recognition sequences that are probably targets for a common recombinase[2]. Evidence has been presented suggesting that rearrangement of specific classes of segments is regulated by modulation of their accessibility to the recombinase[3]. To elucidate mechanisms which control V-region gene assembly, we have investigated the effect of flanking gene expression on the frequency at which introduced V-gene segments are assembled in pre-B cell lines. Our findings suggest that transcription may play a direct role in the regulation of immunoglobulin V-gene assembly.

Transformation by Abelson murine leukaemia virus (A-MuLV) generates pre-B cell lines; during culture some lines

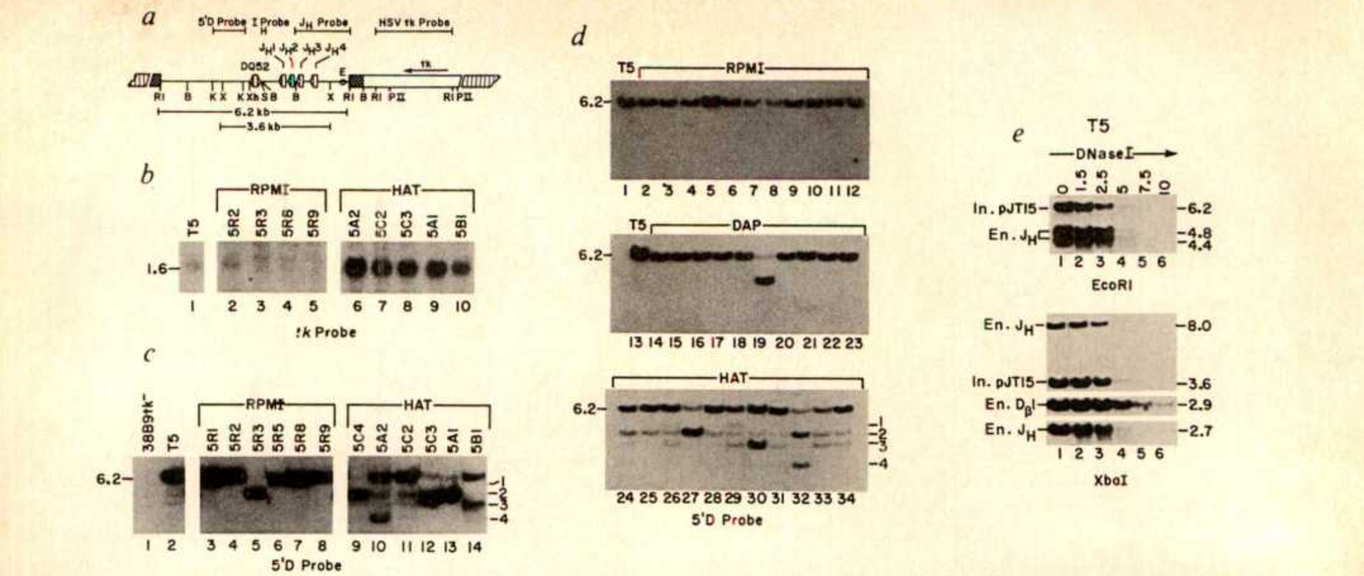

Fig. 1 Activation of transfected heavy-chain *V*-gene assembly. a, Map of the T5 integration. Line, murine DNA; checked box, plasmid DNA; open box, *tk* DNA; and lined box, cellular sequences. *D* and J_H segments with associated recognition sequences (triangles) are indicated. E, the heavy chain enhancer; arrow, *tk* gene. Restriction endonuclease sites are as follows: RI, *Eco*RI; B, *Bam*HI; K, *Kpn*I; X, *Xba*I; Xh, XhoI; S, *Sac*I; PII, *Pvu*II. *b*, *tk* expression in T5 derivatives. Total RNA (10 μg) from the cell lines indicated was assayed by Northern blotting for hybridization to a ^{32}P-labelled HSV *tk* probe as described[3]. *c*, Rearrangement of the integrated substrate. Genomic DNA (10 μg) from cell lines indicated was digested with *Eco*RI and analysed by Southern blotting for hybridization to a ^{32}P-labelled 5'D probe as described[4]. *DQ*52 to J_H 1-4 rearrangements are indicated by 1-4. *d*, Substrate rearrangements in T5 subclones isolated in RPMI (lanes 2-12), DAP (lanes 14-23) and HAT (lanes 23-34). *e*, DNase sensitivity of the integrated substrate. Nuclei isolated from T5 were incubated with 0-10 μg ml^{-1} of DNase I as described[2]. Genomic DNA (10 μg) was digested with either *Eco*RI or *Xba*I, hybridized to the J_H and D_B1 (ref. 2) probes, and assayed as in *c*. Endogenous (En.) and substrate (In.) fragments are indicated. Densitometry revealed that in lane 4 the pJT15 substrate and the 2.7-kb endogenous J_H-containing fragment retain 6 and 10%, respectively, of their lane 1 signal intensity, whereas the endogenous D_B1-containing fragment retains 81%. Fragment sizes are in kb.

Methods. The 38B9*tk*⁻ cell line has been described[4]. T5 was derived by CaPO$_4$ co-transfection of 5×10^7 38B9 *tk*⁻ cells with pJT15 and pSV2neo, followed by selection in G418 (ref. 4). HAT- or DAP-resistant clonal T5 derivatives were isolated in 24-well plates by plating 10^4-10^5 cells per well in 5×10^{-5} M DAP or in HAT[4]. For DNase sensitivity assays, T5 and 5R9 were expanded in RPMI and 5B1 in HAT.

assemble endogenous immunoglobulin *V*-region genes[1]. The Abelson line 38B9*tk*⁻ has been shown to assemble endogenous and transfected heavy-chain *V*-gene segments[4]. To examine the effect of local gene expression on rearrangement activity, a substrate (pJT15) containing *DQ*52 and J_H segments plus the heavy-chain enhancer downstream from a herpes simplex virus thymidine kinase (*tk*) gene was introduced into 38B9*tk*⁻ by unlinked co-transformation[4]. We used transfected clone T5, which had integrated a single copy of pJT15 (Fig. 1). As observed in 38B9 cells transfected with other *tk*-based constructs[4], *tk* messenger RNA was barely detectable in T5 cells (Fig. 1*b*, lane 1; see below). To isolate rare cells that expressed the *tk* gene, T5 populations were plated in HAT (hypoxanthine, aminopterin and thymidine) medium[4]; HAT-resistant clones occurred at a frequency of 10^{-4} to 10^{-5}, and all expressed normal 1.6 kb (kilobase) *tk* RNA from the *tk* promoter (Fig. 1*b*, lanes 6-10). Clones isolated in non-selective medium did not appear to express *tk* mRNA (Fig. 1*b*, lanes 2-5). The ability to isolate *tk*-expressing variants from transfected populations formed the basis of our experiments.

The region 5' of *DQ*52 (5'D probe, Fig. 1*a*) has been deleted from the 38B9 genome through endogenous joining[4] (Fig. 1*c*, lane 1). Thus, in T5 derivatives, the unrearranged pJT15 substrate was detected as a 5'D-positive, 6.2-kb *Eco*RI fragment (Fig. 1*c*, lane 2). In a given T5 cell, the *DQ*52 segment may join to any of the four J_H segments in the substrate; therefore, rearrangements which occurred during expansion of T5 subclones were detected as a mixture of four smaller, rearrangement-specific 5'D-positive *Eco*RI fragments (Fig. 1*c* and 1*d*). Five such rearranged fragments were molecularly cloned; sequence analysis indicated that all contained normal DJ_H joins (Fig. 2), some of which contained N regions[5]. Insertion of N regions into DJ_H rearrangements within the pJT15 construct correlated with terminal deoxynucleotidyl transferase RNA levels in clonal derivatives of a single line (Fig. 2), providing the strongest evidence to date linking this enzyme with N-region addition[2,5].

Genomic DNA from the initial T5 population contained a very low but detectable level of specific rearrangements (Fig.

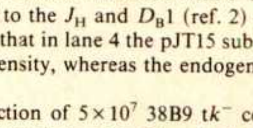

Fig. 2 Nucleotide sequences of *DQ*52 to J_H joins. *Eco*RI fragments hybridizing to the 5'D probe but not the I probe (Fig. 1*a*) were isolated from Charon 16A libraries of 5A2, 5B1 and I12 DNA as described[4]. Joins isolated from terminal deoxyribosyl transferase (TdT)-positive (+) and TdT-negative (−) lines are noted; nucleotide sequences were determined as described[4]. Recognition heptamers are underlined, and joins aligned with germline sequences so that bases lost during joining are apparent. Asterisks, N regions. Lower right panel: Total RNA from the lines indicated was assayed for hybridization to a TdT cDNA clone as described[2]. The TdT transcript and its approximate size in kb are indicated.

Table 1 Substrate rearrangement correlation with HAT resistance

	Experiment no. 1		Experiment No. 2		Experiment No. 3		Experiment No. 4		Total	
	RPMI	HAT	RPMI	HAT	RPMI	HAT	RPMI	HAT	RPMI	HAT
Subclones examined	7	5	6	9	11	11	11	11	35	36
Unrearranged	4	0	5	0	10	2	10	0	29	2
Single rearrangement	2	0	1	0	1	1	0	0	4	1
Rearranged*	1	5	0	9	0	8	1	11	2	33

*DQ*52 to J_H joining was assayed in clonal T5 derivatives in four separate experiments.

* A level of *DQ*52 to J_H joining within the population at or greater than that of Fig. 1*d*, lane 4.

1*c*, lane 2), suggesting the presence of a minor subpopulation that had joined introduced *D* and J_H segments. Clonal populations derived in RPMI did not express the *tk* gene or show evidence of substrate rearrangement (Fig. 1*c* and *d*); a few tk^- clones had a single *D* to J_H join (Fig. 1*c*, lane 5) demonstrating that *D* to J_H rearrangement *per se* did not initiate expression of the contiguous *tk* gene (Fig. 1*b*, lane 3). Such joins probably occurred before subcloning, as cells containing the 6.2-kb unrearranged substrate were absent. In contrast, *tk*-expressing clonal populations isolated in HAT medium displayed a striking level of rearrangement within the substrate (Fig. 1*c* and *d*). Most HAT-resistant clonal populations also contained many cells with an unrearranged 6.2-kb substrate, indicating each cell derived from a progenitor that expressed an unrearranged *tk* substrate, and that joining occurred during expansion of the population (Fig. 1*c* and *d*). Subcloning of initial HAT-resistant clones confirmed that *D* to J_H joining within the substrate occurred frequently in *tk*-expressing derivatives (not shown). HAT resistance (*tk* expression) was correlated with rearrangement of the introduced *D* and J_H segments in four separate experiments (Table 1).

To investigate whether increased recombination frequencies in HAT-resistant cells were associated with *tk* expression rather than other potential effects of selection (such as interference with nucleotide metabolism), T5 cells were also grown in 2,6-diaminopurine (DAP) which selects against cells expressing adenosine phosphoribosyl transferase[6]; conditions were employed such that survival frequency in DAP was less than in HAT. Surviving clones (Fig. 1*d*, lanes 14–23) showed low levels of rearrangement, as did those derived in RPMI (Fig. 1*d*, lanes 2–12). Therefore, the increased frequency of *DQ*52 to J_H rearrangement in HAT-resistant clones is associated specifically with expression of the flanking *tk* gene.

The 'active' chromatin state required for expression of eukaryotic genes is reflected by its sensitivity in isolated nuclei to digestion with DNase I (DNase sensitivity)[7,8]. To define the requirements for *V*-gene assembly further, we examined relative DNase sensitivity of the pJT15 construct in the nuclei of the T5 line, the HAT-derived 5B1 line (which expresses the *tk* gene and actively rearranges the substrate) and the RPMI-derived 5R9 line (which does not express the *tk* gene or rearrange the substrate). In all three the DNase sensitivity was similar to that of the active endogenous J_H loci; all were DNase sensitive relative to the inactive[2] D_B1 locus of the T-cell receptor (Fig. 1*e*, lanes 1–6; only T5 data are shown). Thus, DNase sensitivity *per se* is not responsible for active rearrangement of the introduced construct.

To analyse further the basis for low frequency expression of introduced HSV *tk* genes in 38B9 and the relationship between increased *tk* expression and recombination in HAT-resistant derivatives, we analysed a 38B9 *tk*-transformant, L1, which contained multiple intact integrations of a construct containing $V_\lambda 1$ and $J_\lambda 1$ elements flanking a *tk* gene (pLT2, Fig. 3*a*). In this case, transformation was accomplished by unlinked co-electroporation[2]. Assuming that low frequency expression of a co-transfected *tk* gene in 38B9tk^- derivatives resulted from a '*cis*-acting' transcriptional modulation, it would be expected that HAT selection would isolate a population of cells which expressed the *tk* gene in only one of the integrated substrate copies. Because expressed and non-expressed construct copies can be distinguished (see below), we could directly compare the effect of differential expression on rearrangement activity of identical constructs within single cells. Although the 38B9 line is in the heavy-chain phase of its *V*-region gene assembly programme and does not rearrange endogenous λ light chain genes at a detectable level, earlier evidence suggests that all immunoglobulin gene segments are rearranged by a common recombinase[2]; therefore, introduced λ gene segments, if accessible, should be rearranged in this line. Integrated pLT2 copies were detected in genomic DNA of L1 derivatives as $V_\lambda 1$-positive *Pvu*II fragments of different sizes; a *V–J* rearrangement (for example VJ1, Fig. 3*c*) was detected as a $V_\lambda 1$-, $J_\lambda 1$-positive *Pvu*II fragment 1.7 kb smaller than the $V_\lambda 1$-positive *Pvu*II fragment containing the copy from which it was derived (for example RC1, Fig. 3*c*). Nucleotide sequence analysis of a *VJ*1 join molecularly cloned from L1HB confirmed that it occurred by the normal mechanism (Fig. 3*d*).

A population of L1 cells that expressed the introduced *tk* gene was isolated in HAT (L1H, Fig. 3*b*); these HAT-resistant cells again appeared at a frequency of 10^{-4} to 10^{-5}. With respect to integrated construct copies, the genomic DNA of the L1H population appeared identical to that of L1 except for complete loss of a substrate copy which was identified by a 4.5 kb $V_\lambda 1$-positive *Pvu*II fragment (see Fig. 3*c*). Assuming a common recombinase[2], deletion of the expressed *tk* gene(s) as a result of V_λ to J_λ joining within the construct would be expected to be the major mechanism of BUdR(bromodeoxyuridine)-resistance in these lines[4]. Removal of L1H from HAT (L1HT, Fig. 3*b*) followed by selection in BUdR yielded the tk^- population L1HB. These cells had completely rearranged a single integrated construct (RC1) to its product *VJ* join (*VJ*1) (Fig. 3*c*, lanes 3 and 7), whereas other full length copies remained intact. This identifies RC1 as the *tk* copy expressed in this subclone and confirms that the *tk* mRNA found in HAT-resistant subclones derives from a single integrated substrate. This rules out potential post-transcriptional (*trans*-acting) mechanisms for increased *tk* expression that would affect expression from all copies, and strongly suggests that low frequency expression of transfected *tk* genes in these lines is mediated at the transcriptional level.

To identify independently pLT2 construct loci that are expressed, we measured relative DNase sensitivity of the integrated constructs. L1H was expanded in non-selective medium, generating population L1HT2 (Fig. 3*b*), in which RC1 undergoes rearrangement (Fig. 3*e*, lane 1; see below). In L1HT2, both RC1 and its rearranged product *VJ*1 are clearly DNase sensitive relative to endogenous genes and non-rearranging pLT2 integrations (Fig. 3*e*, lanes 1–6). This provides additional evidence that *tk* expression occurs primarily from RC1 in L1H and that activation of this copy is at the transcriptional level. Significantly, after a brief passage in non-selective medium, L1H cells converted the RC1 integration to its derivative rearrangement; however, no rearrangement of other integrated copies was observed (Fig. 3*c*, lanes 4 and 8). Thus, the transcribed construct copy has a high rate of rearrangement but non-expressed copies in the same line do not; this is not because of defects in their

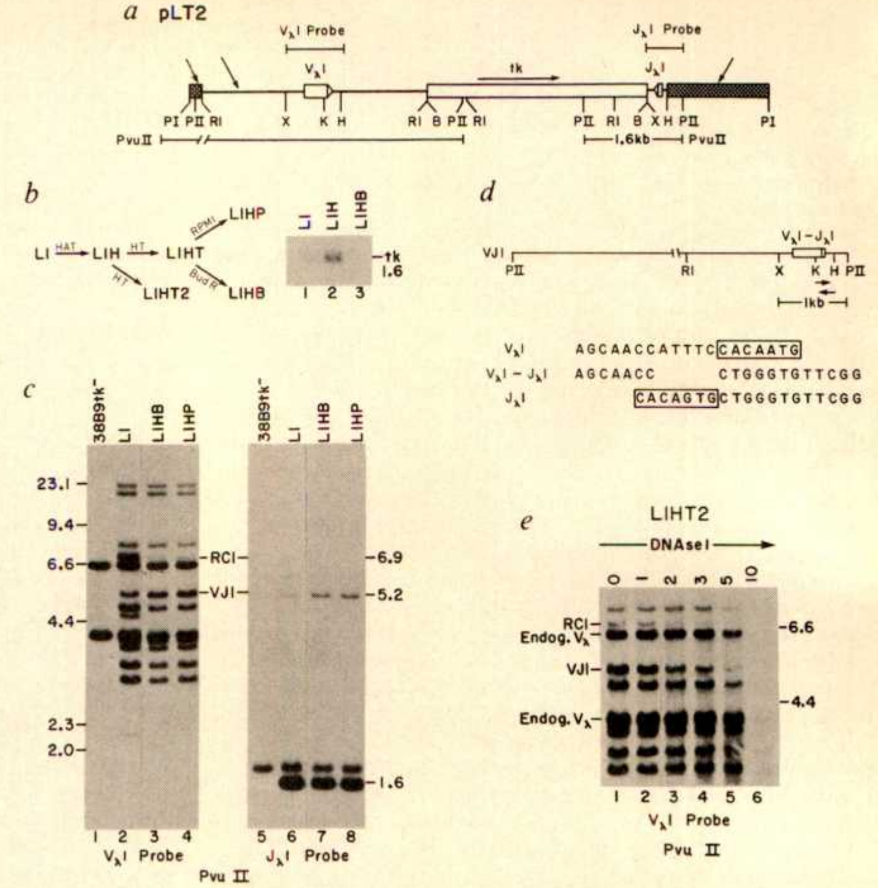

Fig. 3 Rearrangement of transcribed light chain substrates. *a*, Map of the pLT2 substrate. Structures and restriction endonuclease sites as in Fig. 1*a* (also H, *Hin*dIII; PI, *Pvu*I). Arrows above map, regions within which pLT2 copies integrated into cellular DNA. *b*, Selection of L1 derivatives and *tk* expression. Total RNA (10 μg) was assayed for *tk* expression as in Fig. 1*b*. *c*, Rearrangement of the pLT2 substrate. Genomic DNA (10 μg) was digested with *Pvu*II and analysed as in Fig. 1*c* for hybridization to the probes indicated. Sizes are in kb. *d*, Restriction map and nucleotide sequence of a *VJ*1 rearrangement. To isolate this join, L1HB genomic DNA was digested with *Pvu*II, *Eco*RI linkers added and fragments cloned into Charon 16A and screened with $V_\lambda 1$ and $J_\lambda 1$ probes. The join is aligned with germline sequences so that the bases lost are apparent. *e*, DNase sensitivity of integrated and endogenous (Endog.) λ loci. Nuclei from L1HT2 were digested with 0–10 μg ml^{-1} of DNase I; genomic DNA was then digested with *Pvu*II and assayed for hybridization to the $V_\lambda 1$ probe as described in Fig. 1*c*. Fragments corresponding to RC1, *VJ*1 and the endogenous V_λ loci are indicated. Densitometry revealed that in lane 4, RC1 and *VJ*1 retained 17 and 36%, respectively, of their lane 1 signal intensity. In lane 4 the pLT2 copy which is slightly larger than RC1, and the endogenous 6.4-kb V_λ-containing fragment retained 87 and 97%, respectively, of their original intensities. Sizes are in kb.

Methods. pLT2 was derived from pUC13. pLTRneo contains the TN*5neo* resistance gene transcribed from a Moloney-MuLV LTR promoter. L1 was derived by electroporation[2] of 7.5×10^6 38B9 tk^- cells with 10 μg of pLTRneo and 40 μg of pLT2 which had been linearized with *Pvu*I. Transformants were isolated in G418 as in Fig. 1*a*. L1 was passaged through HAT, HT and 10^{-4} M BUdR as described[4]. Other analyses were as described in Figs 1 and 2.

structure, as some different copies were expressed and rearranged in independent L1 derivatives (not shown).

Identical *tk*-based recombination substrates are expressed frequently (>25%) when introduced into myeloma (J558) or L cell lines by the same procedures (not shown) that lead to infrequent expression (10^{-4}–10^{-5}) in pre-B lines. This may be related to the relatively low transformation frequency of pre-B lines[4]. Current results suggest that the block in pre-B cells is transcriptional but does not result from lack of general DNase sensitivity (Fig. 1) or obvious methylation-related phenomena (not shown). Significantly, we found no site-specific recombination events in L cell or J558 transformants when they were subjected to analyses identical to those described above (data not shown), suggesting that recombinase activity may be regulated with respect to stage and tissue specificity. The assay would have detected recombinase activity 3–4 orders of magnitude lower than found in several pre-B cell lines. However, many more different lines must be assayed to verify this point.

In T5 derivatives, the pJT15 substrate is of equivalent DNase-sensitivity to the endogenous J_H loci regardless of *tk* gene expression (Fig. 1*e*); this sensitivity is probably conferred by the associated heavy-chain enhancer[9–10] which is active in pre-B cells[11]. Therefore, activity of the enhancer element (and DNase-sensitive structure *per se*) on the pJT15 substrate appears insufficient to confer direct activation of *D* to J_H rearrangement. T-cell receptor *V*-gene segments introduced into 38B9 within an *expressed tk*-based recombination substrate were DNase sensitive and had a high spontaneous rearrangement rate[2]. In the λ substrate which did not contain known enhancer elements, DNase sensitivity (and rearrangement) appeared to occur only in association with transcription of the *tk* gene. Apparently, efficient assembly of *V* segments requires either transcription or factors closely associated with transcription. Our results do not preclude a regulatory role for enhancer elements with respect to rearrangement; they may allow transcription or closely-associated events which then promote rearrangement. The lack of a clear function for known or potential products of germline immunoglobulin or T-cell receptor gene transcripts supports a direct role for transcription[1]. A relationship between local gene expression and recombination has been observed in the context of other genomic rearrangement events, such as the yeast mating-type locus switch[12] and the immunoglobulin class switch [13,14]. Transcription could influence accessibility for rearrangement in several ways. The recombination mechanism might involve transcription itself; for example DNA unwinding by RNA polymerase[15] could be required for initiation of recombination. Alternatively, transcription of these loci might be associated with structural or nuclear locational changes in DNA that are not detected by general DNase sensitivity and not solely mediated by the enhancer[8,16].

Effect of mutations at the lariat branch acceptor site on β-globin pre-mRNA splicing *in vitro*

H. Hornig, M. Aebi & C. Weissmann

Institut für Molekularbiologie I, Universität Zürich,
8093 Zürich, Switzerland

Introns are excised from full-length transcripts (pre-messenger RNAs) of eukaryotic genes in two steps[1,2]. First, the pre-mRNA is cleaved at the 5′ splice site and a branched (lariat) intermediate is formed[1-6]. Then, cleavage at the 3′ splice site and ligation of the two exons leads to the release of the lariat intron. The intron sequence which accepts the 5′ end to form the lariat branch is strictly conserved in yeast[7-9], but shows more variation in eukaryotes[10,11]. To investigate the requirements for branch formation in eukaryotes further, we have studied *in vitro* splicing of a rabbit globin gene intron with mutations of the normal branch-accepting adenosine nucleotide. We conclude that all four nucleotides can serve as branch acceptors, but that A and C are preferred to G and U in lariat formation. Mutation of the normal A to G or U can lead to an A residue one nucleotide upstream of the normal branch site being used instead. Only branches to A or C participate efficiently in the second splicing step.

Lariat formation[1-5] results from the 2-5′ linkage of the 5′ end of the intron to an adenosine residue close to the 3′ splice site[6]. In the case of yeast nuclear pre-mRNA splicing, efficient lariat formation depends stringently on the strictly conserved TACTAAC-box, where the underlined 3′-proximal A residue serves as branch acceptor[4,5]. Deletions or point mutations within this sequence abolish splicing[7-9]. In contrast, the branch acceptor sequence of higher eukaryotes is poorly conserved[10,11] and deletions of this sequence lead to the activation of cryptic branch points which allow normal splicing, albeit at a reduced rate[12,13]. There seems to be a distance constraint as regards branch formation, in that the acceptor sequences identified so far lie within 18-37 nucleotides upstream of the 3′ splice site[11,12].

The branch acceptor nucleotide of the large rabbit β-globin intron has been determined *in vivo*[3] as well as *in vitro* [13] to be predominantly the underlined A residue and to a lesser extent the A residue preceding it, in the sequence GCTAAC. In order to study the nucleotide requirement at the branch point, we have converted the principal branch acceptor A residue (position 1,036)[14] to either G, C or T by site-directed mutagenesis. The mutated β-globin sequences (*Bam*HI-*Sma*I fragments, Fig. 1*A*) were substituted for their wild-type counterparts in plasmid SP64/RchrβG[13], which allows *in vitro* synthesis of a globin pre-mRNA containing both the small and the large intron (Fig. 1*A*). Wild-type, as well as the three mutant pre-mRNAs 1,036 A→G, 1,036 A→C and 1,036 A→T, yielded the correctly-spliced product of 536-nucleotide length when spliced *in vitro* (Fig. 1*B*). The rate of splicing of the large introns of the mutants, as determined within the linear period of the reaction (60-120 min), was about 50% that of wild type (Table 1). In the case of the mutant substrates 1,036 A→G and A→T a slight accumulation of the lariat intermediate of the large intron relative to the lariat product was observed (Fig. 1*B*).

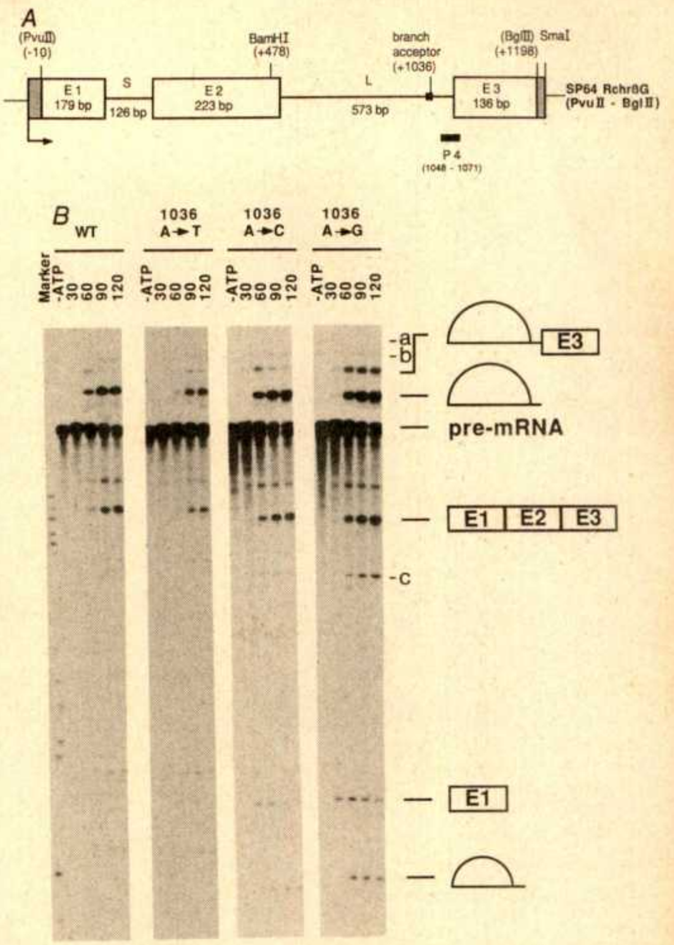

Fig. 1 Analysis of the *in vitro* splicing products of pre-mRNAs with branch acceptor mutations. *A*, Partial map of the *Pvu*II-*Bgl*IIRchrβG DNA fragment[14] cloned into pSP64 for synthesis of pre-mRNA *in vitro*. The construction of the wild-type plasmid has been described[13]. Numbering is relative to the natural cap site (+1). Initiation of transcription is indicated by an arrow. Point mutations at position 1,036 were obtained by oligonucleotide-directed mutagenesis[19]. The mutated *Bam*HI-*Sma*I fragments were substituted for their wild-type counterparts and the resulting plasmids used as template for *in vitro* synthesis of pre-mRNA[22,23]. The resulting transcripts contained 24 and 3 nucleotides of polylinker sequences at the 5′ and 3′ ends, respectively. The location of the oligonucleotide primer used in primer elongation is shown. The drawing is not to scale. *B*, *In vitro* splicing of wild-type and branch-point-mutant pre-mRNA. The ^{32}P-UMP-labelled pre-mRNA (specific activity 2×10^6 c.p.m. pmol^{-1} RNA) of the wild type and the mutants indicated above each panel were incubated with HeLa-cell nuclear extract[6,24] for the time (min.) indicated, and analysed on a 3.2% denaturing polyacrylamide gel[25]. The relevant products and intermediates are indicated; for a description of structures a (superlariat intermediate), b (superlariat) and c (E1-E2), see refs 13 and 19. '-ATP', ATP and creatine phosphate omitted and the RNA incubated with HeLa-cell nuclear extract for 120 min. Marker, 5′-^{32}P-labelled *Bsp*I-digested pBR322.

As shown previously[13], the exact position of the branch point can be determined by primer extension analysis using the 24-nucleotide *primer 4* complementary to the region 1,048-1,071 (ref. 14), which is 12 nucleotides downstream of the branch acceptor A nucleotide (Fig. 1*A*). Reverse transcription of branched RNA molecules, either the excised lariat intron or the lariat intermediate containing the third exon, is arrested at the position of the branch[2]. Wild-type RNA yields a major primer extension product, indicative for the branch at position 1,036 (ref. 13) and a minor product extending to position 1,035, the

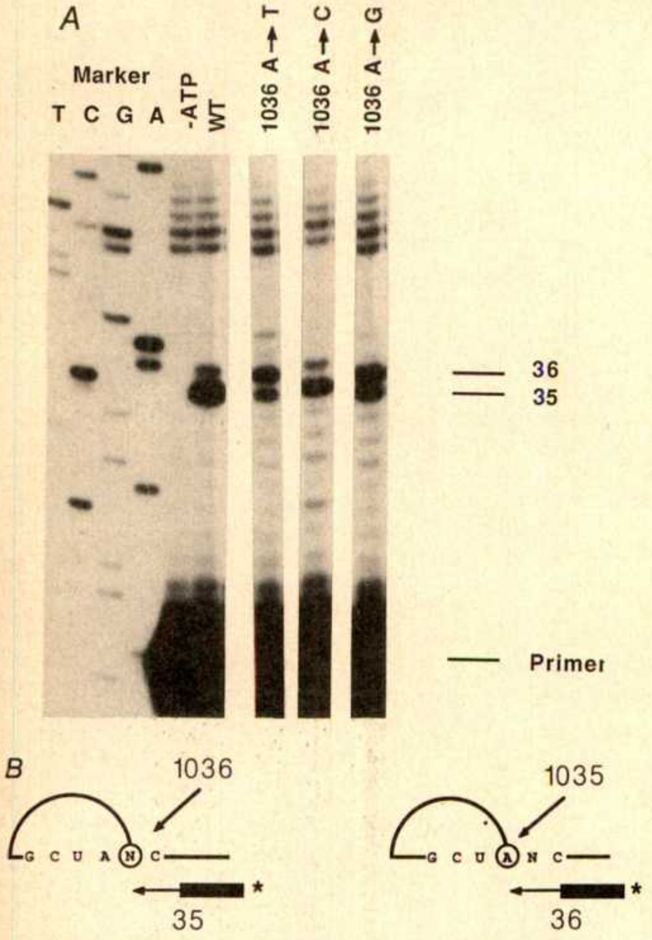

Fig. 2 Analysis of branch point use by primer extension. *A*, Wild-type and mutant pre-mRNA (0.1 pmol each) were incubated with HeLa-cell nuclear extract and RNA was extracted after 1.5 h. For annealing of the 5′-^{32}P-labelled 24-nucleotide *primer 4* (specific activity 4×10^6 c.p.m. pmol^{-1}) and primer extension using reverse transcriptase, see ref. 13. Extension products were analysed on a 12% denaturing polyacrylamide gel[25]. Marker, dideoxy chain termination sequence[26] of single-stranded M13 mp8 RchrβG (*Bam*HI-*Eco*RI) using the universal N15 primer[27]. *B*, Scheme of the expected primer extension products indicative for branch-point formation at position 1,036 and 1,035. Black box, 5′-^{32}P-labelled primer (*, position of label).

Table 1 Relative rate of splicing and use of different branch points

Nucleotide at position 1,036 (N)	Relative rate of splicing	Relative use of branch point 1,036 GCUAⓃ C–	1,035 GCUⒶ NC–
A(wt)	100%	90%	10%
T	60%	35%	65%
C	45%	85%	15%
G	55%	40%	60%

The nucleotide N (in DNA) was substituted with the nucleotides listed in column 1. Appropriate bands were cut out of a polyacrylamide gel like the one in Fig. 1*B* and counted in a liquid scintillation counter. The relative splicing rate was calculated from the ratio of fully spliced product E1-E2-E3 to small lariat intron at different times. The rate of excision of the first intron is independent of the rate of excision of the second intron, as determined by quantifying the data in Fig. 3 of ref. 19, and can therefore serve as a reference value. This ratio is taken as 100% for the wild type. To calculate relative branch point use, the two primer extension products (Fig. 2*A*) indicative for the two branch points were excised from the gel and the radioactivity was determined. wt, wild-type nucleotide.

A residue immediately 5′ to the major branch point (Fig. 2*A*, *B*), in a 10:1 ratio (Table 1). In the case of the mutant pre-mRNAs 1,036 A→T and A→G, about 60% of the branches were displaced to the A residue at position 1,035, while the remaining 40% were connected to the mutated nucleotide at position 1,036 (Fig. 2*A*, Table 1). The 1,036 A→C mutant yielded predominantly C-branched molecules (85%), while the neighbouring upstream A-nucleotide was used in 15% of the lariat molecules. We conclude that all four nucleotides can serve as branch acceptors, albeit with different efficiencies, namely A > C > G, U.

Since in the above experiment a mixture of lariat intermediate and lariat product had been analysed, it was not clear whether the molecules that were branched at the mutated nucleotide were capable of undergoing cleavage and exon joining at the 3′ splice site, or whether they accumulated as dead end lariat intermediates. We isolated the lariat product as well as the lariat intermediate by polyacrylamide gel electrophoresis. In the case of wild type, lariat intermediate and lariat product yielded the same pattern of primer extension products (Fig. 3): the A residue at position 1,036 was the major branch acceptor in both cases. Different results were obtained with the two mutants 1,036 A→G and 1,036 A→T: whereas the lariat products were branched almost exclusively at the A residue (position 1,035) immediately upstream of the mutated position, the lariat intermediate was branched predominantly at the mutated position itself. In contrast, the lariat intermediate and lariat intron derived from the mutant pre-mRNA 1,036 A→C yielded mainly lariat product branched at the mutated residue (Table 2). This analysis assumes that the lariat products of all the pre-mRNAs examined are equally stable in the *in vitro* system and are therefore representative of the processed lariat intermediates. We believe this to be the case because the ratio of lariat product to mature mRNA was about the same for the wild type and all the mutants throughout the reaction (Fig. 1*B*). We have also determined that the deproteinized mutant lariat products are more resistant to debranching by nuclear extract than the wild-type lariat (the relative rates decrease in the order wild type >1,036 A→T, 1,036 A→G > 1,036 A→C), however, as native lariats are resistant to debranching[15], this finding is not necessarily relevant to the question of selective degradation.

We conclude from these results that lariat intermediate branched at a C-nucleotide is functional in the second step of the splicing reaction, whereas G- or U-branches are strongly inhibitory.

This observation is in agreement with the results of Wallace and Edmonds[16], who reported that the predominant branched nucleotide in nuclear RNA was an A residue. In contrast to previous reports, more detailed analysis revealed that branched C-residues were the next most frequently found (J. C. Wallace and M. Edmonds, personal communication). Moreover, a naturally-occurring C-branched lariat of the first intron of the human growth hormone pre-mRNA has been identified (K. Hartmuth and A. Barta, personal communication).

An A→G transition of the branch acceptor of the small intron of the human β-globin gene has been shown to lead to a fivefold reduction of the splicing efficiency *in vitro*[12]. The mutated branch acceptor nucleotide (37 nucleotides upstream of the 3′ splice site) was not used in lariat formation. Instead, a cryptic branch acceptor sequence 24 nucleotides upstream of the 3′ splice site was activated. The difference between these results and ours may be due to the fact that different introns were examined in the two studies. The affinity of the original branch acceptor sequence for the human β-globin small intron to the component recognizing it may be weaker than that of the rabbit sequence we have studied. Further weakening of this affinity by an A→G transition of the branchpoint might lead to the use of a cryptic site which has a more favourable sequence and/or is closer to the 3′ splice site. There seems to be no stringent sequence

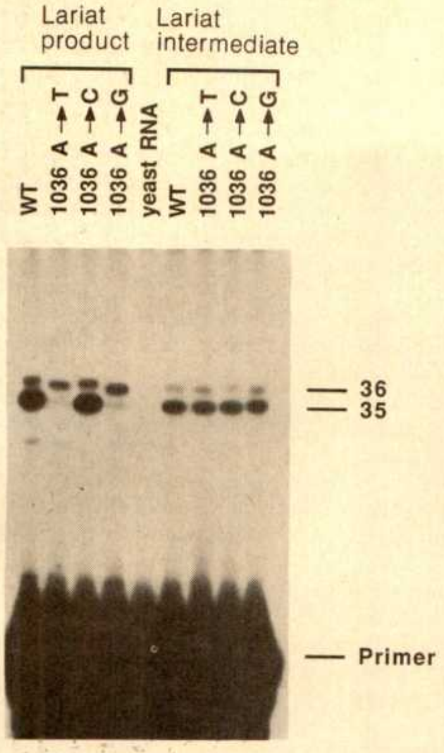

Fig. 3 Branching in lariat product and lariat intermediate derived from pre-mRNAs with branch point mutations, analysed by primer extension. Wild-type and mutant pre-mRNAs (4 pmol each) were spliced *in vitro* as described in Fig. 1. Lariat product and lariat intermediate were isolated by preparative polyacrylamide gel electrophoresis and analysed by primer extension using the 5'-^{32}P-labelled *primer 4* (see Fig. 1*A*). The 35- and 36-nucleotide extension products indicate branch points at positions 1,036 and 1,035, respectively (see Fig. 2*B*). Yeast RNA was used as carrier RNA and served as a negative control.

requirement for branch acceptor sequences, as indicated by the variety of natural and cryptic branch acceptor sequences reported to date[12,13].

All mutations of the branch acceptor A of the rabbit β-globin large intron led to a 50% reduction in the rate of splicing as compared to wild type. Since complex formation around the branch acceptor sequence is an early step in the splicing reaction[17,18], the observed rate in the three mutant RNA splicing reactions may be caused by a lower affinity of the splicing components for the branch acceptor sequence, or by a decreased rate of branch formation. Our results do not allow us to differentiate between these two possibilities. As the branch is nevertheless formed at the mutated position or at the A-nucleotide just upstream of the normal branch site, and no activation of cryptic branch acceptor sequences is detected, we conclude that the mutated sequence is still functional, which confirms that there is no stringent sequence requirement for branch formation. Although an A- or C-residue is favoured over G or U, branch formation is possible at all four nucleotides. In the case of the mutants, preference for an A residue may cause the activation of the A-nucleotide at position 1,035, one nucleotide upstream of the normal branch site, as branch acceptor.

It is surprising that the sequence requirements for the first step of the splicing reaction, where the branch region is intimately involved, are lower than for the second step, where it is at a distance from the reacting nucleotides. In the first step, recognition of the branch-forming region by splicing components may not be stringent, and /or the reactivity of the branch-forming nucleotide as regards its capacity of attacking the phosphodiester bond upstream of the 5' terminal G residue of the intron may not be very sequence specific. It is even possible that assembly of the nucleoprotein complex at the branch-forming region takes place at a fixed distance from the polypyrimidine stretch at the end of the intron, regardless of the actual sequence at that position, and that branch formation occurs from the closest suitable nucleotide.

Table 2 Different frequencies of branchpoints in lariat products and lariat intermediates

Nucleotide at position 1,036 (N)	Relative use of branch point			
	Lariat product		Lariat intermediate	
	1,036 GCUAⓃC	1,035 GCUⒶNC	1,036 GCUAⓃC	1,035 GCUⒶNC
A(wt)	80%	20%	80%	20%
T	10%	90%	80%	20%
C	80%	20%	90%	10%
G	20%	80%	80%	20%

The primer extension analysis of Fig. 3 was quantified by cutting the cDNA corresponding to different branch points out of the gel, and determining the radioactivity in a scintillation counter. wt, wild-type nucleotide.

As regards the second step of splicing, it is not immediately clear why 3' cleavage and exon joining should be affected by a mutation at the branch point, which is some 20-30 nucleotides upstream of the 3' cleavage site. It is important to note that certain mutations at the 5' end of the β-globin large intron, namely those converting the 5' GT to AT, GA and GG, also prevent the second step of splicing, while allowing the first[19]. A similar observation has been made for a yeast 5' GT→AT mutant[20]. In yeast, moreover, the requirements at the branch point (TACTAAC) are apparently even stricter than in higher eukaryotes, because an A→C substitution of the branch acceptor nucleotide not only slows down branch formation to the C-residue but very strongly reduces the second step of splicing[21]. It would thus seem that at least three nucleotides close to the branch, namely the branch point nucleotide and the two closest residues linked to it via the 2'-5' linkage, are required for the second splicing step. This requirement could come about either because a component that binds to the branch region in connection with the first splicing step does not undergo an essential conformational change, or fails to dissociate or translocate or because a component required for the second step of the splicing reaction is unable to recognize the mutated sequence.

The correct activation of *Antennapedia* and bithorax complex genes requires the *fushi tarazu* gene

P. W. Ingham* & A. Martinez-Arias

Medical Research Council, Laboratory of Molecular Biology,
Hills Road, Cambridge OX1 3PS, UK

In the *Drosophila* embryo the establishment and specification of metameric units depends upon the selective activation of the segmentation[1,2] and the homoeotic selector genes[3,4]. The former are necessary for establishing the appropriate number of metameric[2] or parasegmental[5] units, whereas the latter control the pathways of differentiation followed by particular parasegments[3,4]. Classical embryological manipulations[6,7] have shown that these processes must be closely coordinated during normal development. However, previous studies of pair-rule genes have led to the suggestion that the specification of segmental identity proceeds independently of the establishment of metameres as physical units[1,8]. These apparently conflicting perspectives can be reconciled by envisaging a common maternally derived positional information system which is independently interpreted by the components of both processes[6,9]. In the case of the partitioning process, the gap and pair-rule genes would be instrumental in translating this information, whereas the activation of the homeotic genes would be mediated via other intermediaries[4,10] (see ref. 9 for review). It is difficult to see, however, how such a system could ensure the precise regulation of the two types of genes implicit in the final differentiated pattern. This difficulty has led to the suggestion that the segmentation mechanism must define the precise boundaries of selector gene expression[11]. Here we confirm this suggestion and propose that the gene *fushi tarazu* plays a key role in this process, integrating the processes of metameric partitioning and regional specification in the *Drosophila* embryo.

The gene *fushi tarazu* (*ftz*)[2,12], a member of the pair-rule class, differs from the other members of the class in two interesting ways: it is located in the Antennapedia-complex (ANT-C)[13], one of two major clusters of selector genes, and it contains a class I homoeobox[14,15], which is present in and highly conserved between the ANT-C and bithorax-complex (BX-C) selector genes[14-16]. These characteristics have led to the suggestion that *ftz* is itself a homoeotic gene[17,18] which, in some unspecified way, regulates the expression of the ANT-C and BX-C genes[15]. Here we test these proposals and argue that *ftz* plays a dual role in the *Drosophila* blastoderm; in common with other pair-rule genes, it is necessary for the correct spatial regulation of segment-defining genes[19] for example *engrailed*, (*en*). In addition, we present evidence that it is necessary for the correct activation of homoeotic genes.

During normal embryogenesis the establishment of parasegmental units is first seen by the appearance of fourteen stripes of *en* activity along the antero-posterior axis of the early gastrula[19-21]. Shortly afterwards these stripes come to lie at the anterior margin of fourteen metameric units which can thus be defined as parasegments (PS)[5,22] (Fig. 1*a*). The specification of parasegments is illustrated at this stage by the distribution of selector gene products[5,16,23-26,28,29]. The *Ubx* proteins, for example, show a characteristic heterogeneous pattern between PS5 and PS13[27], defining a metameric repeat or 'Ubx-metamere'[28]; in the wild type these metameres coincide with parasegments and PS6 displays a characteristic higher intensity and more even distribution of proteins than other parasegments (see Fig. 1*b*).

In the extended germ band, *ftz*$^-$ embryos are partitioned into seven double-width parasegments[17] and lack all the even-numbered engrailed stripes[19] (Fig. 1*c*). At the same stage, embryos mutant for another pair-rule gene *odd paired* (*opa*), are similarly malpartitioned, though vestiges of the even numbered stripes of engrailed do remain (S. DiNardo and P. O'Farrell, personal communication; Fig. 1*e*). If the specification of parasegments is independent of their establishment, as previously suggested[1,8,9], the malpartitioning observed in *ftz*$^-$ and *opa*$^-$ embryos would be expected to generate parasegments of compound identity (see Fig. 2). To investigate this possibility we have analysed the distribution of *Ubx* proteins in *opa*$^-$ and *ftz*$^-$ embryos.

In embryos mutant for *opa*, the pattern of *Ubx* protein distribution in the double-sized units reveals them to be of composite character, the anterior half behaving as an odd-numbered parasegment and the posterior as an even-numbered parasegment. This is particularly clear in the case of the PS5/6 unit, in which the posterior half exhibits high levels of *Ubx* protein typical of the wild type PS6 (Fig. 1*f*). Each of the three more posterior double units displays defects in the *Ubx* pattern that are attributable to *opa* effects on segment polarity genes (unpublished data).

By contrast, the *Ubx* protein pattern in *ftz*$^-$ germ bands is quite different both from *opa* and wild type. The PS5/6 double unit has a staining pattern typical of the wild type PS5, except for a narrow strip of cells at the posterior border that show levels characteristic of a more posterior parasegment (but not PS6). The next double unit exhibits *Ubx* staining characteristic not of PS6 but of PS7-12, as so the next two double units, whereas the last double unit resembles PS13. The main feature of this pattern is that there are half the number of parasegments and half the number of Ubx-metameres. Both units coincide, and the *ftz*$^-$ embryos can be considered to consist of a chain of large odd-numbered parasegments: 3*, 5*, 7*, 9*, 11*, 13* (Fig. 1*d*).

Thus the two mutations *opa* and *ftz*, which result in similar malpartitioning of the germ band, show radically different patterns of *Ubx* expression within three hours of the blastoderm stage. The absence of PS6-specific *Ubx* staining in *ftz* germ bands cannot be accounted for by the elimination of PS6 cells, as little if any cell death has occurred in the ectoderm by this stage (unpublished observations). Rather, it suggests a failure in the specification of the metameric unit at blastoderm. We therefore monitored the initiation of *Ubx* expression in *ftz*$^-$ blastoderms.

An interesting and unexpected feature of the initial expression of *Ubx* in normal embryos is a transient pair-rule distribution of *Ubx* transcripts reminiscent of and in the same frame as that of *ftz*[11,23] (see Fig. 3). This discontinuous pattern is superimposed on a broader continuous distribution of transcripts. *Ubx* transcripts do accumulate in the *ftz*$^-$ blastoderm, but show a continuous distribution, with some modulation in the dorsal region (Fig. 3), but without the peak of accumulation ventrally or laterally in the anlage of PS6 that is the first sign of the pair-rule modulation in the wild type. Accumulation of transcript begins slightly posterior to the position of PS6 and probably reflects the wild-type early continuous distribution. At onset of gastrulation in wild-type embryos three further peaks of *Ubx* transcript[11,23] appear which correspond to PS8, PS10 and PS12 (Fig. 3); in *ftz*$^-$ embryos *Ubx* expression remains homogeneous at this stage. By the end of gastrulation, when the pair-rule modulation is normally still clearly visible, the pattern of *Ubx* expression reveals three unusually large and similar units reflecting the malpartitioning of the embryo and probably corresponding to the 7*, 9* and 11* parasegments described above (Fig. 3*f*).

To determine whether there is a requirement for *ftz*$^+$ in the activation of other selector genes we have studied the initiation of expression of the *Sex Combs Reduced* (*Scr*) and *Antennapedia* (*Antp*) loci in *ftz*$^-$ embryos. Expression of both genes also shows a transient pair-rule modulation in the late blastoderm[25,26]. In the wild type there is a strong peak of *Scr* expression in PS2

---

* Present address: Imperial Cancer Research Fund, Developmental Biology Unit, Department of Zoology, South Parks Road, Oxford, OX1 3PS, UK.

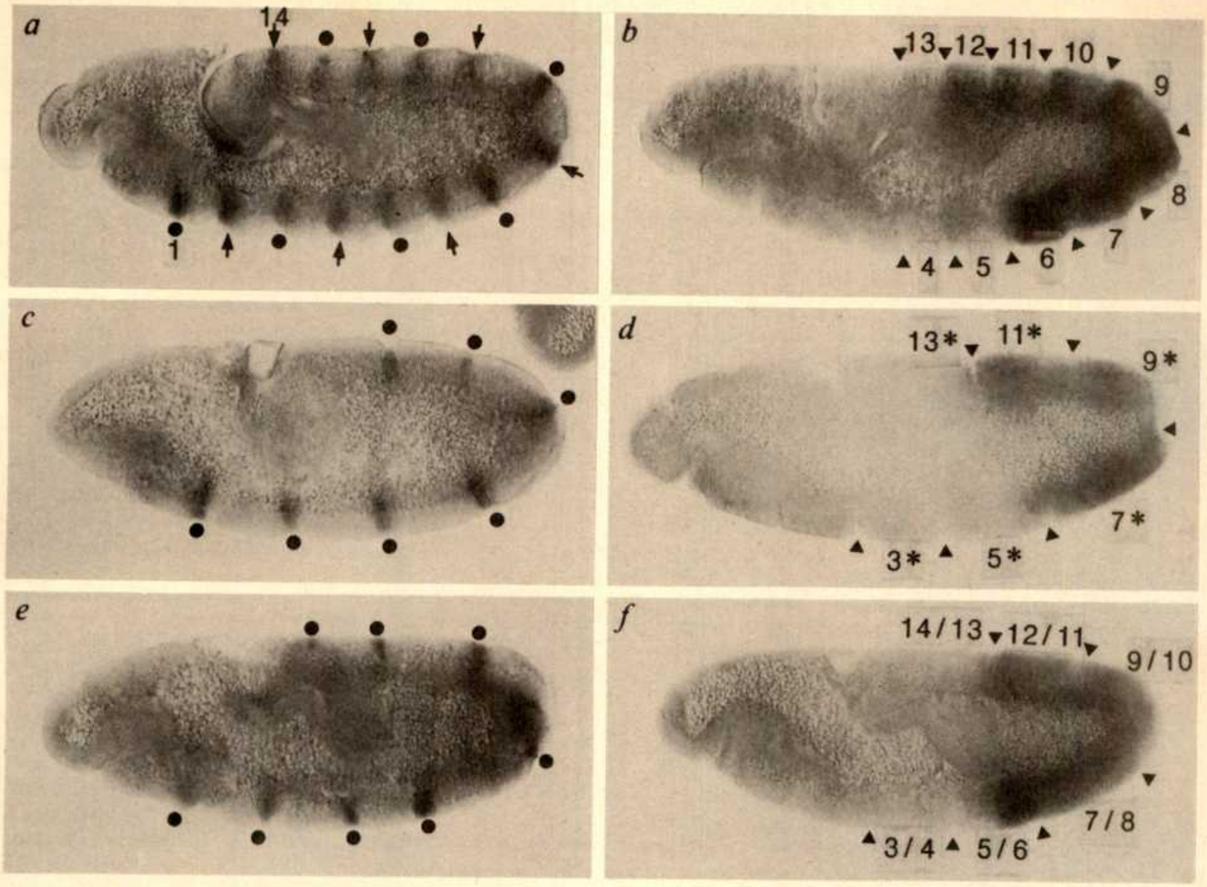

Fig. 1 Coupled and uncoupled partitioning and specification of parasegments visualized by *en* and *Ubx* protein distribution in wild-type and mutant embryos. *a*, Wild-type extended germ band showing bands of *en* protein (1–14), each of which is located at the anterior margin of the odd numbered (small dots) and even numbered (arrows) parasegmental units; *b*, wild type extended germ band showing typical *Ubx* protein distribution. The highest levels of staining are in PS6; PS7–12 show very similar patterns with higher levels posteriorly than anteriorly. PS5 has only limited expression around the tracheal pit and expression in PS13 is also restricted[23,27]; *c*, ftz^- extended germ band stained with *en* antibody. The embryo is subdivided into seven double sized units and only the odd-numbered *en* stripes are present; these are of approximately the same width as wild type, in agreement with previous transcriptional data[19]. *d*, embryo similar to that shown in *c* stained with antibody for *Ubx*. There is no staining characteristic of the wild type PS6. The most anterior unit which expresses *Ubx* appears as an enlarged PS5, with the exception of a few cells at its posterior margin which show a higher level of staining. The following three units have patterns typical of single parasegments, which would correspond to 7*, 9* and 11*; *e*, opa^- extended germ band stained with *en* antibody. Like the ftz^- germ band, it is composed of half the normal number of double width parasegmental units, only of the odd-numbered *en* bands are present. However, vestiges of even-numbered bands are often visible, especially in the mesoderm. *f*, Embryo similar to that shown in *e*. A single segment periodic pattern of *Ubx* staining similar to that of wild type is superimposed on the malpartitioned embryo which is composed of half the wild-type number of double segment units. Note especially that the PS5–6 unit shows staining characteristic of the wild type PS5 and PS6. The deviations from wild type in the more posterior parasegments can be explained by the effects of segment polarity genes on *Ubx* (unpublished observations).

Methods. Embryos were stained with monoclonal antibodies against *en*[20] and *Ubx*[41]. The staining procedure is similar to that described elsewhere[27], except that the second antibody was biotinylated, allowing the use of peroxidase conjugated to a biotin-avidin system (Vectastain kit; Vector laboratories). The stain was visualized with diamino benzidine according to instructions from the suppliers. In these and subsequent experiments, we used three alleles of *ftz*: a deficiency *Df(3R)4Scb*, a point mutant, ftz^{9H34} (ref. 42), and an insertion ftz^{W20} (ref. 18). In the case of *odd paired* a single allele opa^{5H97} (ref. 42) was used.

and six weaker peaks corresponding to even-numbered parasegments. This initial pattern of *Scr* expression is completely abolished in ftz^- embryos (Fig. 4*c*).

Expression of *Antp* from the P2 promoter is first detectable in a four-cell-wide peak which corresponds in position to the primordium of PS4 in the late blastoderm[26], this peak is not present in ftz^- embryos at the same stage (Fig. 4*b*). Transcripts from the P2 promoter only appear in ftz^- embryos during late gastrulation, when they are restricted to the presumptive ectoderm in a region corresponding to PS3 and PS4 (data not shown). This is similar to *Antp* expression in wild-type PS3[26] and is likely to correspond to PS3*. The pattern of *Antp* expression from the P1 promoter is not altered in ftz^- embryos (unpublished observations).

These results suggest that *ftz* plays a fundamental role in differentiating between the even- and odd-numbered parasegments by modulating the activation of the selector genes in the blastoderm. Although the unique identity of each parasegment is controlled by selector genes, the genes themselves are generally expressed in more than one parasegment[16,23–29]. A striking feature of the presumptive gnathal and thoracic region of the embryo at blastoderm (and the central nervous system during later embryonic stages), is that the even-numbered parasegments are the primary sites of expression of different selector genes[23–26]. Thus *Scr* is expressed at highest levels in PS2, *Antp* in PS4 and *Ubx* in PS6; mutations in each of these genes transform their preferred parasegments but not the other even-numbered ones. By contrast, both genetic analysis and expression patterns suggest that the odd-numbered parasegments depend on more than one selector gene for their correct development. Different parasegments thus come to be distinguished both by different combinations and different levels of selector gene activity. Both PS4 and PS5, for instance, express *Antp*, but this expression differs between the two, both in spatial pattern and amount. This

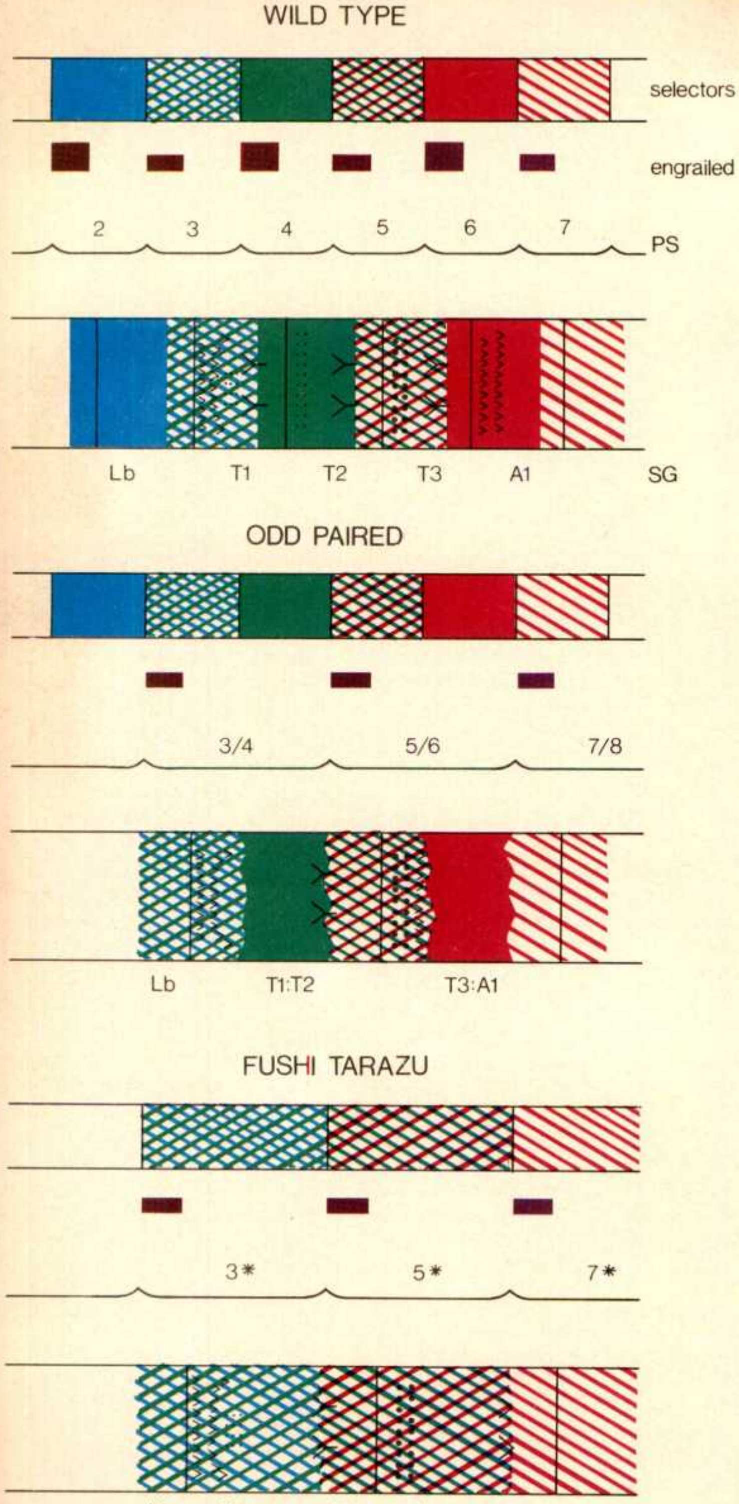

Fig. 2 Schematic representations of the embryonic development in wild type and each of the mutants. Colours indicate activity of selector genes: blue, *Scr*; green, *Antp* and red, *Ubx*. Cells in even-numbered parasegments express a single selector gene in a rather homogeneous pattern. Odd numbered parasegments display complicated patterns with more than one selector gene expressed at high levels in areas not demarcated by compartment boundaries[23-26] (indicated by hatching). Notice how segments are derived from parasegments by shifting the position of the grooves; this occurs during muscle attachment after germ band shortening[5]. In the wild type, segments are thus composed of two adjacent parasegments. In the mutants, this is also true but the selector gene distribution in them results in enlarged segments with rather different identities from wild type. The two different mutant situations illustrated will result in different cuticular phenotypes. In the case of *opa*, where partition and specification are uncoupled, anterior compartments are composed of cells of two different identities; this in turn generates larval cuticular denticle bands of composite segmental character, as observed in *opa*$^-$ larvae[2]. The wavy boundaries represent the observed variability of the phenotype. In the case of *ftz*, where partition and specification are coupled, anterior compartments have a single identity; the final phenotype thus corresponds to the precise elimination of alternate parasegments[2]. Notice that our observations and interpretations contrast sharply with former interpretations of these phenotypes[2], which suggest that the phenotypic differences between *opa* and *ftz* directly reflect a requirement in different but overlapping regions; this requirement would correlate with the site of expression of the gene. In our view, the phenotypes reflect the fundamental differences in the functions rather than the spatial depolyment of both genes.

difference is maintained by *Ubx*, as in the absence of *Ubx*, PS5 (and PS6) now develop like PS4 and express *Antp* accordingly[30,31]. These differences between *Antp* expression in the primordia of PS4 and PS5 are, however, apparent in the late blastoderm stage, long before *Ubx* product could possibly act and indeed in the absence of the *Ubx* gene[29]. It follows that the parasegmental modulation of *Antp* must be established independently of *Ubx* and only subsequently maintained by interactions between selector genes. Similarly *Scr*, which is required and expressed in PS2 and PS3, is expressed at high levels only in the PS2 primordium at blastoderm, whereas *Ubx* is expressed at high levels in the PS6 primordium at the same time.

The peaks of selector gene activity thus seem to differentiate between the even-numbered and odd-numbered parasegmental domains from the onset of their expression. The results presented here show that the patterns of *Scr*, *Antp* and *Ubx* all depend on *ftz* activity; in the absence of *ftz* products none of the peaks are established. This does not prevent the subsequent expression of any of these genes, but the absence of the initial modulation is reflected in the later failure to establish differences between PS3 and 4, 5 and 6 and so on in *ftz*$^-$ embryos. A prediction of this interpretation is that expression of *Scr* and *Antp* extends further posteriorly than normal, so that *Scr* now becomes expressed in cells which would normally have given rise to PS4,

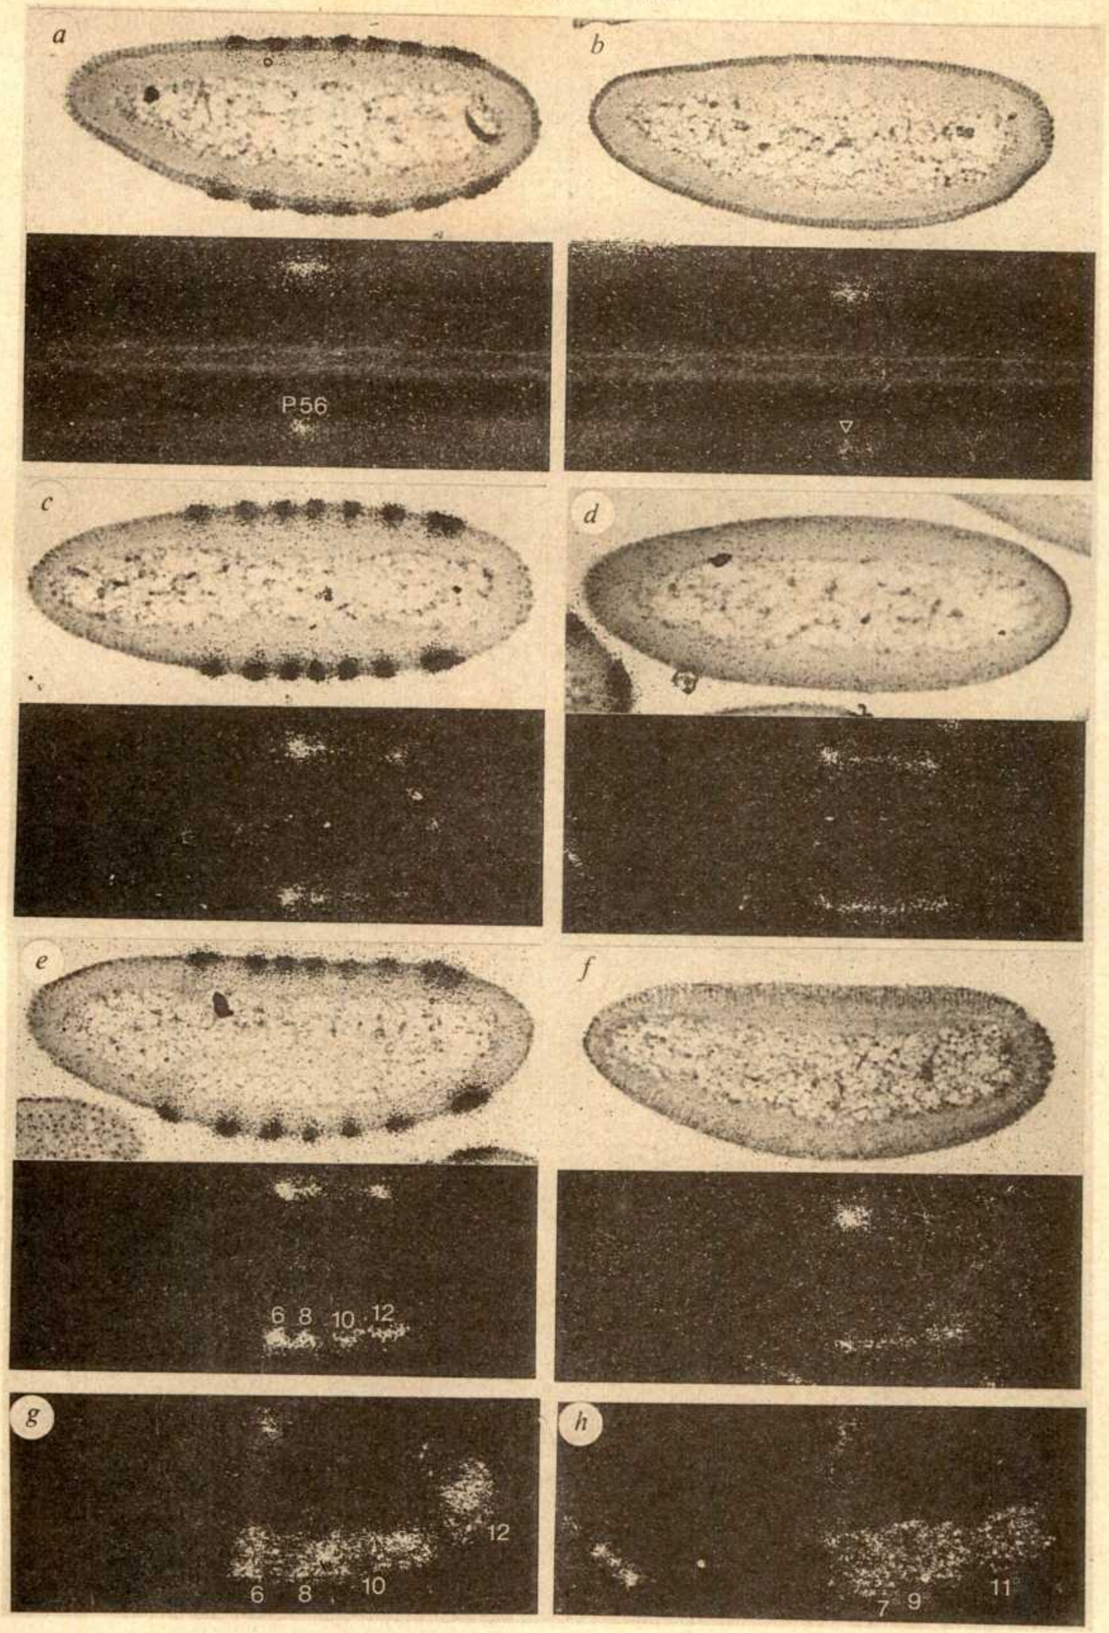

Fig. 3 Initiation of *Ubx* transcription in wild type and *ftz*$^-$ embryos. Panels *a–f* show bright field images of sections hybridized with ^{35}S-labelled *ftz* probe revealing the *ftz* embryos and dark field images of adjacent sections hybridized with ^{35}S-labelled *Ubx* probe. *a*, Wild type; a peak of *Ubx* transcript is first detectable dorsally and ventrally in a region corresponding to PS6; *b*, *ftz*$^-$ embryos at the same stage; there is no clear peak of transcript ventrally and laterally (arrowed). *c*, Slightly older wild type embryos show rather high levels of *Ubx* transcript in PS6, with a low background of transcription extending posteriorly; *d*, no such peak is observed laterally or ventrally in *ftz*$^-$ embryos. *Ubx* transcript is however detected at low levels in a broad domain from 20% to 50% egg length. *e*, With the onset of gastrulation in wild type three further peaks appear[11,23], corresponding to PS8, 10 and 12; *f*, in *ftz*$^-$ embryos, however, the expression ventrally remains more or less uniform. *g*, *h*, dark field images of *Ubx* labelling in late gastrulae. In wild type the pair-rule modulation persists, the label revealing the presumptive parasegments 6, 8, 10 and 12. In *ftz*$^-$ embryos, by contrast, the label reveals three adjacent units which probably correspond to the 7*, 9* and 11* parasegments shown in Fig. 3. The *in situ* methods used are similar to those described elsewhere[43]. The *ftz* probe spans all the *ftz* coding region[43]; the *Ubx* probe corresponds to the A122 fragment[23], and in Northern blots detects a 4.7-kilobase (kb) RNA.

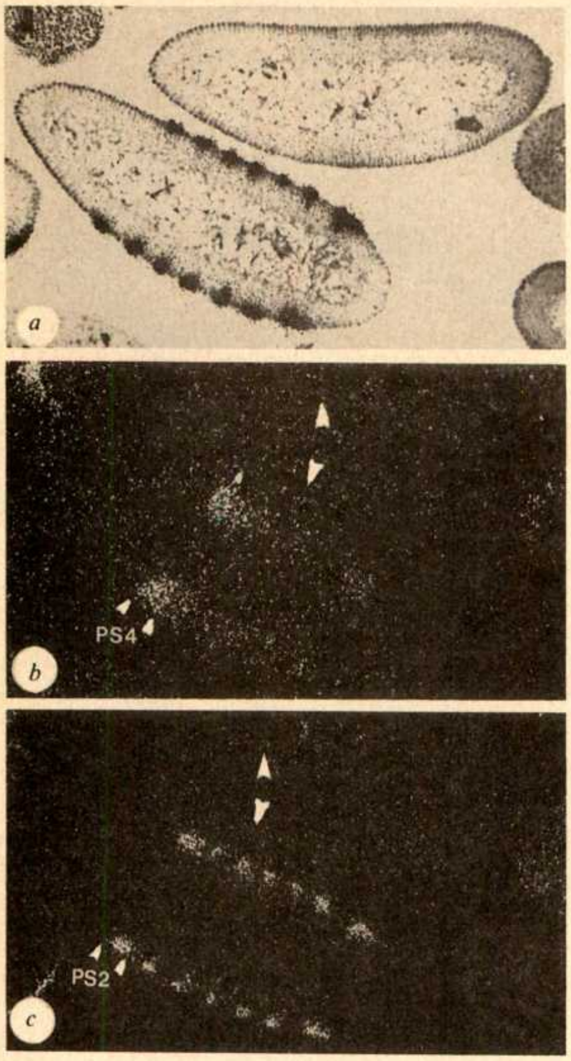

Fig. 4 Expression of *ftz*, *Antp* and *Scr* in wild type and *ftz*^{W20} blastoderms. *a*, Saggital sections through wild type (lower) and *ftz*^{W20} (upper) late stage 14 embryos hybridized with ^{35}S-labelled *ftz* probe. The wild type shows the typical pattern of seven discrete bands of transcript accumulation. The mutant shows very low levels of transcript accumulation which show a weak pair-rule modulation. *b*, Dark field image of adjacent section to *a* hybridized with a ^{35}S-labelled probe specific for the *Antp* P2 transcript. This reveals accumulation of high levels of transcript in the cells of the PS4 primordium in the wild type, but not in the same region of the *ftz*^{W20} embryo (arrowed). *c*, Dark-field image of adjacent section to *a* hybridized with a ^{35}S-labelled probe derived from the 5' end of the *Scr* transcription unit. In the wild type, *Scr* transcript accumulates in seven stripes which correspond in their position and size to those of *ftz* transcript. Transcript accumulation is higher in the most anterior of these, which corresponds to the primordium of PS2. In the *ftz*^{W20} embryo there is no detectable expression of *Scr* at this stage, either in PS2 (arrowed) or more posteriorly. The *Antp* probe is a fragment from the proximal part of the gene; at blastoderm it specifically detects transcripts from the P2 promoter[26]. Methods as in Fig. 3.

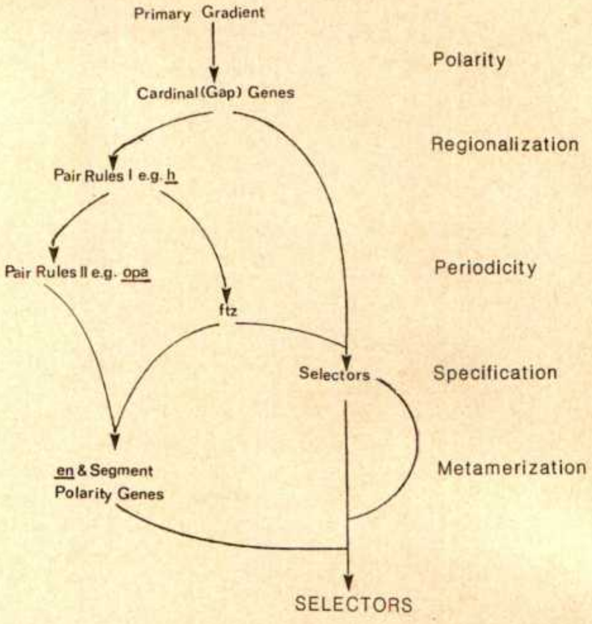

Fig. 5 A summary of the hierarchial interactions which lead to the integrated partitioning and specification of the *Drosophila* embryo. Arrows indicate the regulatory relationships between different classes of genes. The processes proposed to be accomplished by each step are indicated on the right. A primary gradient of maternally derived morphogen(s) establishes 'polarity' and, as the blastoderm begins to form, instructs the deployment of the cardinal or gap genes[40]. This results in the 'regionalization' of the embryo, that is, the establishment of the broad domains of potential selector gene expression. The cardinal genes also act to establish 'periodicity' by organizing the expression of a subset of the pair-rule genes, exemplified by *hairy* (*h*)[32]. The function of this class is to pattern *ftz*, and also, we surmize, other pair-rule genes such as *opa*. This step-by-step subdivision of the embryo is translated into an array of parasegments that are uniquely specified, primarily by the activation of both *en* and the ANT-C and BX-C genes by *ftz*. The 'specification' and 'metamerization' of parasegments takes place as the blastoderm forms into cells. Later, the interactions indicated elaborate the pattern of selectors to that of the first instar larva. This elaborated pattern of selector gene expression is represented by capital letters.

whilst *Antp* is expressed in cells which would normally make PS6. This implies that in the wild type the peaks of expression serve to differentiate between parasegments by establishing specific levels or states of selector gene activity in the cells of the even-numbered parasegments. These states subsequently make these cells refractory to the expression of the more anteriorly expressed selector genes. This close linkage of the selector gene pattern with *ftz* expression is emphasized by the finding that it is maintained in embryos mutant for the gap genes *Kr*, *kni* and *hb* all of which alter the pattern of *ftz* expression[32,33].

Previous analyses have demonstrated a functional non-equivalence of the pair-rule genes, some being required for normal expression of *ftz* whilst others are not[19,34]. These findings led to the proposition that parasegments are established by a hierarchy of interactions between pair-rule genes resulting in the establishment of the pattern of *en* expression[19]. We propose a further subdivision of the pair-rule class distinguishing between those genes that are responsible only for the partitioning process (for example, *opa*) and *ftz*, which acts both to partition and to specify the cells of the blastoderm. Thus, the processes of partitioning and specification of the *Drosophila* embryo are integrated through a hierarchical network of interactions between the different segmentation genes (see Fig. 5).

As *ftz* itself is expressed in a reiterated pattern throughout the presumptive germ band, it is clear that it cannot alone account for the differential activation of the selector genes. There must therefore be specific activators which allow *ftz* to discriminate between the selector genes in different regions of the blastoderm; candidates for such activators are the zygotic gap or cardinal genes[1,2] whose products are distributed in broad though restricted domains[35] and whose absence has been shown to affect selector gene expression[27,32,33]. Consequently, understanding the correlation between the metameric pattern and selector gene expression demands a consideration of the possible molecular interactions between *ftz* and the cardinal gene products.

The data available[32,33] suggest that an interaction between *ftz* and cardinal gene products is responsible for the activation of selector genes, the *ftz* product providing the precise spatial specificity and the gap gene products the promoter specificity. One possibility is that *ftz* and the cardinal products are activators; the specificity of selector gene expression would then result from a simple combination of their activities. An alternative envisions a maternally encoded repressor common to all selector genes and bound at the sites of cardinal gene activity. The role of *ftz* would be to compete out this repressor and thus make the underlying pattern of cardinal gene activity available to selector genes; in this possibility the role of *ftz* in activation, though crucial, would be indirect.

Our model contrasts with those previously proposed in which a primary gradient, maternally encoded, is directly responsible for the activation of the homoeotic selector genes[4,39]. Although there is good evidence for the existence of such gradients[6,36–38], it seems unlikely that they can have the instructive capacity required for the short range detailed patterning that precisely orders selector genes in the zygote. They can, however, as suggested by Meinhardt[40], have instructive capacity in broader, less precisely defined ranges, and may activate the cardinal genes. Thus, the ultimate effect of such gradients on the selector genes would operate through the aforementioned hierarchy (Fig. 5) and ultimately rely on their indirect effect on *ftz*.

We thank M. Akam for encouragement and many critical discussions, C. Cabrera, D. Hogness, K. Howard, P. Lawrence and K. Nasmyth for interest and discussions, C. Nüsslein-Volhard, G. Jürgens and T. Kaufman for mutant stocks and M. Scott for ANT-C probes. We thank M. Eggo, B. Cross and A. Donoughue for typing. A.M.-A. was supported by an EMBO long-term fellowship.

Note added in proof: Results compatible with our conclusions have recently been reported by Duncan, I. M. *Cell*, **47**, 297–309 (1986).

Does nuclear integration of mitochondrial sequences occur during senescence in *Podospora*?

France Koll

Centre de Génétique Moléculaire, Centre National de la Recherche Scientifique, 91190 Gif-sur-Yvette, France

Observations in various organisms[1–3] suggest that the transfer of mitochondrial DNA sequences to the nucleus has occurred in the course of evolution. Wright and Cummings have reported[4], on the basis of hybridization experiments, that there is such a transposition in the fungus *Podospora anserina* during senescence[5] (arrest of vegetative growth) which is accompanied by amplification of specific mitochondrial sequences[6–9]. They suggested that this transposition could explain senescence, and, as it could be regularly observed under laboratory conditions, senescence in *Podospora* could constitute a model system to study the molecular mechanisms of the transfer of DNA sequences from mitochondria to the nucleus. We report here experiments similar to those of Wright and Cummings[4] but include additional critical controls. Our results do not confirm the data of Wright and Cummings; the only positive signals we observed after hybridization of mitochondrial DNA sequences on nuclear DNAs can be attributed to contaminating DNA from mitochondria or plasmids.

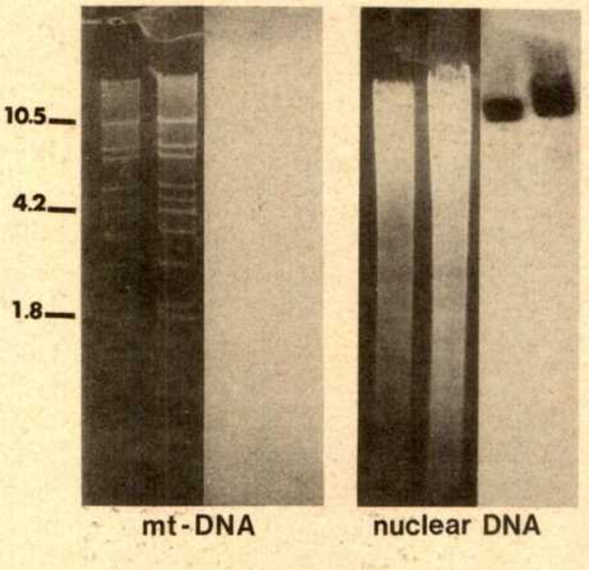

Fig. 1 Detection of a unique nuclear sequence. *a*, Wild-type strain; *b*, *mex1* strain. Nuclear and mt DNAs obtained from a total DNA extract[15] after separation on diamidino-phenyl-indole (DAPI)-CsCl buoyant density gradient[7] (3 or 4 cycles). The 1.4-kb nuclear sequence used as probe contained the suppressor gene *su4* of *Podospora* previously selected from a genomic library[19] and was nick-translated[20] with [α-^{32}P]dATP and [α-^{32}P]dCTP (specific activity $\sim 5\times10^7$ c.p.m. μg^{-1}), hybridized as already described[15] with nitrocellulose filters on which restriction digests[21] of the DNAs were transferred according to Southern[22]. Shown here are the autoradiograms observed after hybridization of the 1.4-kb nuclear sequence on the *Bam*HI digestion of ~5 μg nuclear and ~0.5 μg mt-DNA from a young wild-type strain and from the long-lived mutant *mex1* (nuclear DNA complexity: 2×10^7 base pairs (bp); mt-DNA complexity: 9×10^4 bp). The electrophoretic patterns of the DNAs from the wild-type strain are represented in *a* and from the *mex1* strain in *b*. The autoradiograms (2 days exposure at room temperature) are represented in *a'* and *b'*. We detect an 11-kb sequence similar to the probe in the nuclear DNA of each strain. The probe does not hybridize on the mt-DNA. Sizes in kb.

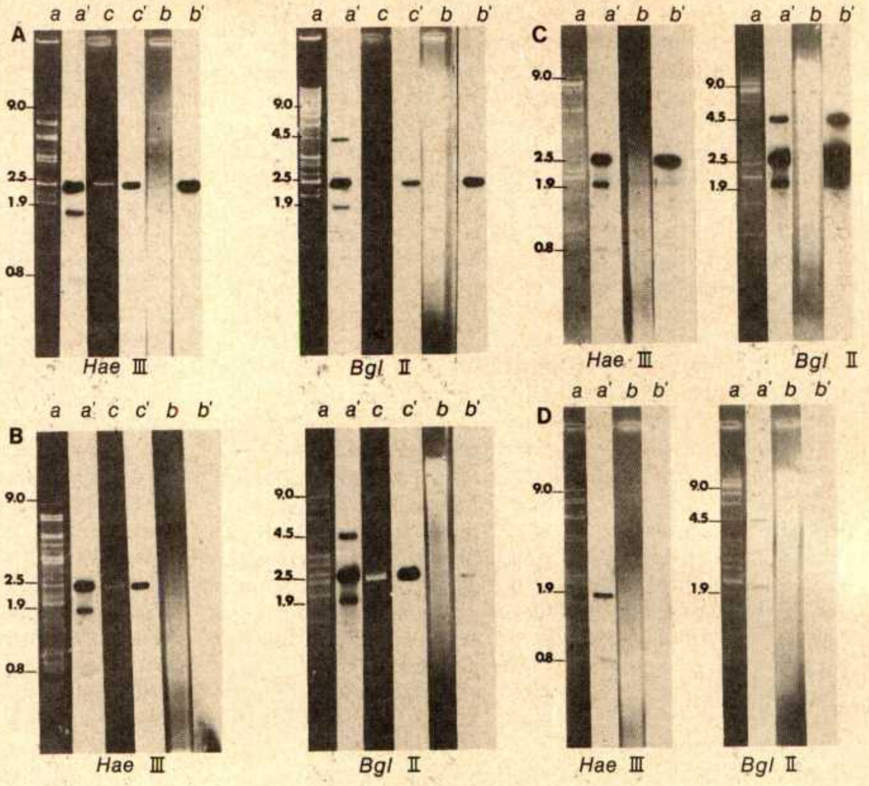

Fig. 2 Hybridization of the α mitochondrial intron on the different DNAs extracted from three independent senescent cultures (A, B, C) and one young *s mt+* (D). Nuclear DNA (density, 1.712 g cm^{-3}), α-free sen-DNA molecules (density, 1.700 g cm^{-3}) and mt DNA (density, 1.694 g cm^{-3}) of each senescent culture were purified by at least three cycles of DAPI–CsCl ultracentrifugation of total DNA extract. Each DNA was digested by *Hae*III and *Bgl*II, electrophoresed on agarose gels, transferred to nitrocellulose filters and hybridized with a ^{32}P nick-translated α purified sequence. The α sequence was purified from the plasmid in which it was integrated by *Bam*HI digestion, electrophoresis on acrylamide gel and electroelution[15]. For both enzymes (*Hae*III, *Bgl*II), the electrophoretic pattern of mt-DNA, α-free sen-DNA molecules and nuclear DNA from a given culture are represented respectively in lanes *a*, *b*, *c* after staining by ethidium bromide (α-sen-DNA extracted from the culture C is not represented). Corresponding autoradiograms after hybridization are shown in lanes *a'*, *b'* and *c'*. For mt-DNA and α-sen-DNA, autoradiograms were exposed for 24 h at room temperature; for nuclear DNAs, they were observed after 4–5 days at −70 °C using two intensifying screens. D, Control experiment showing hybridization of the α sequence on *Hae*III and *Bgl*II digests and corresponding autoradiograms of mt-DNA (*a* and *a'*) and nuclear (*b* and *b'*) DNAs from a young *s mt+* wild type strain. The α mt-sequence used as probe is 2.5-kb long and contains only one site for both enzymes *Hae*III and *Bgl*II. Two fragments (1.9 and 0.8 kb after *Hae*III digest; 4.5 and 1.9 kb after *Bgl*II digest), corresponding to the α sequence integrated in the mitochondrial genome, are labelled after hybridization of the probe on the young mt-DNA (D, lanes *a'* and *b'*). The free α-sen-DNA molecules present in the senescent cultures are circular molecules constituted of tandemly repeated α sequence. Consequently, only one 2.5-kb fragment corresponding to linearized α sequence is observed after digestion of this α-*sen*-DNA by *Hae*III and *Bgl*II (A and B, lanes *c*) and hybridized with the probe (A and B, lanes *c'*). The three labelled bands observed on *Hae*III and *Bgl*II digestion of senescent mt-DNA (parts A, B and C, lanes *a'*) correspond to hybridization of the probe on the α sequence integrated in the mitochondrial genome (1.9- and 0.8-kb fragments on *Hae*III digests; 4.5- and 1.9-kb fragments on *Bgl*II digests) and on linearized free α-sen-DNA molecules always associated with it.

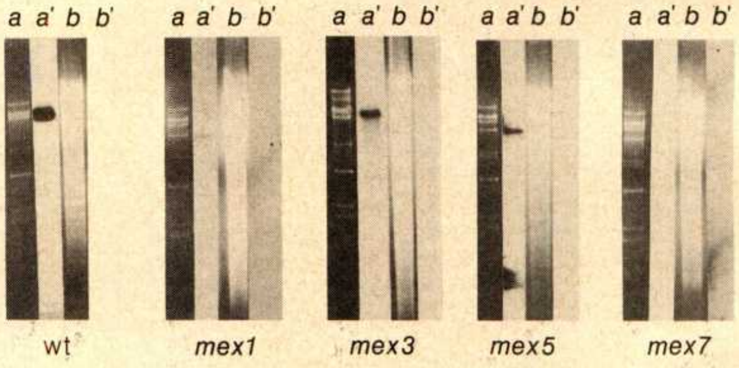

Fig. 3 Hybridization of the α sequence on the nuclear DNA of the mitochondrial long-lived mutants *mex1*, *mex3*, *mex5*, *mex7* and of *s mt+* wild-type strain (wt). The structure of the mt DNA of each mutant has already been described[14,15]: this DNA is deleted for most of the α mitochondrial intron in *mex1*, *mex5* and *mex7* mutants and it is not modified in this sequence in *mex3*. Sequencing data indicate that the *mex5* mt-DNA has retained 387 bp of the α sequence whereas only 32 bp are conserved in *mex1* and *mex7* mt-DNA. The nuclear DNA and mt-DNA of each strain were purified from total DNA extracts after DAPI–CsCl centrifugation. After digestion by *Eco*RI and gel electrophoresis, each nuclear and mt-DNA was transferred to nitrocellulose filters and hybridized with labelled α sequence (see Fig. 2 legend) as in Fig. 1. The electrophoretic patterns of the mt-DNA and of the nuclear DNA are represented in lanes *a* and *b*, respectively, and the corresponding autoradiograms in lanes *a'* and *b'*. These autoradiograms were observed after 4–5 days of exposure of the filters at −70 °C except for the *mex3* and wild-type mt-DNA (24 h at room temperature). Note that the specific activity of the probe and the hybridization conditions were such that the *Eco*RI fragment of *mex1* and *mex7* mt-DNA, which contains only 32 bp of the α sequence could be detected. In these conditions no hybridization was observed on the nuclear DNAs of these mutants.

In *Podospora*, senescence[5] is assumed to be caused by the amplification of some mitochondrial (mt) DNA sequences, called sen-DNAs[7–11]. The most frequently amplified sequence, α-sen-DNA, corresponds exactly to the first intron of the mt-gene encoding the first subunit of cytochrome oxidase[12,13]. We looked for integration of this α sequence into the nuclear genome of three senescent cultures of the wild-type strain *smt+* and in that of four long-lived mitochondrial mutants (*mex1, mex3, mex5* and *mex7*)[14,15]. Note that *mex1*, isolated in our laboratory[10], was reported by Wright and Cummings[4] to contain the α sequence integrated within its nuclear genome.

The nuclear DNA of these different strains was hybridized with the α sequence (Fig. 2) in conditions allowing us to detect a single copy of a nuclear sequence (see Fig. 1 legend). To exclude the possibility that the putative labelled bands could result from hybridization of the probe on contaminating DNAs (mt-DNA or free α-sen-DNA molecules which are found as bands between those of nuclear and mt-DNA in a buoyant density caesium chloride gradient[6,7]), hybridizations were simultaneously performed on mt-DNA and purified α-sen-DNA. Figure 2 shows the results of the hybridization of α sequence on the *Hae*III- and *Bgl*II-restricted nuclear DNA from three independent senescent cultures, A, B and C. Both enzymes have one site in the α sequence. Consequently, we expected to find two or three labelled bands if the α sequence is integrated in the nuclear genome as a single copy or tandem multicopy,

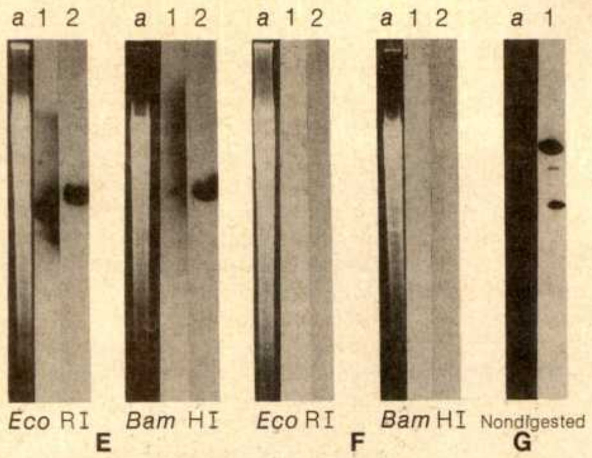

Fig. 4 Hybridization of the purified α sequence and pBR322 DNA on two nuclear DNAs obtained from two independent cultures of the *mex1* mutant. Each nuclear DNA was digested by *Eco*RI and *Bam*HI, transferred to nitrocellulose filter and hybridized with purified α sequence (see Fig. 2) and separately with pBR322 DNA (extracted according to Maniatis *et al.*[20]) used as radioactive probes. For each nuclear DNA samples (E and F), the electrophoretic patterns of the *Bam*HI and *Eco*RI digestions are represented in lanes *a*. The autoradiograms (4–5 days at −70 °C) observed after hybridization of the α sequence and pBR322 DNA are represented in lanes 1 and 2, respectively. On the nuclear DNA E, no hybridization is observed. On the nuclear DNA D, one labelled band is observed with both probes at the same position whatever the enzymes used (*Bam*HI or *Eco*RI). This suggests that these labelled bands result from hybridization of pBR322 or derivative DNA contaminating both the nuclear DNA E and the 'purified' α sequence. Hybridization between pBR322 DNA and purified α sequence, represented in G, confirmed that this purified DNA is contaminated by pBR322. Nondigested pBR322 DNA was electrophoresed, transferred to nitrocellulose and hybridized with the purified α sequence. The electrophoretic pattern of nondigested pBR322 DNA is presented in lane *a* and the corresponding autoradiogram in lane 1. The three forms of pBR322 DNA are detected by the probe.

respectively. In the latter case, one of these bands must be 2.5 kilobases (kb) long as this is the length of the α sequence.

For cultures A and B, we observed a single 2.5-kb labelled band, which we interpret as hybridization on free α-sen-DNA molecules contaminating the nuclear DNAs. For culture C, three labelled bands are observed, one at 2.5 kb, suggesting that head-to-tail copies of α are integrated, and the others, which would correspond to the sequences flanking α, migrate as the mt-fragments that hybridize with the α sequence. Our conclusion, confirmed by using other enzymes (data not shown), is that this nuclear DNA is contaminated both by mt-DNA and by free α-sen-DNA. Such contamination is difficult to avoid, even after three or four cycles of purification on CsCl gradients, because of the small differences in density of the three molecular species recovered from senescent cultures.

Figure 3 shows the results of hybridization of *Eco*RI-restricted nuclear and mt-DNAs of the mutants *mex1, mex3, mex5* and *mex7* with the α sequence which has no *Eco*RI site. Nuclear DNAs did not hybridize with the probe.

Figure 4 represents hybridization of α and pBR322 DNA probes on two different nuclear DNA extracts (E, F) of *mex1*. We found one labelled band at the same position with both probes on nuclear DNA (E) but no label on nuclear DNA (F). The nuclear DNA (E) was probably contaminated by pBR322 or derivative DNA. Contamination by plasmid DNA is fairly common; Shmookleir Reis *et al.*[16] have pointed out the danger of systematic microbial contamination of DNA samples. Indeed, the presence of plasmidic DNA, both in the DNA used as a radioactive probe (even after two cycles of electrophoretic purification[17]) and in the DNA samples tested, led to the appearance of labelled bands that could be misinterpreted in the absence of appropriate controls such as hybridization using the vector alone as probe.

Our experiments, repeated several times, failed to demonstrate any similarity between the α sequence and the nuclear DNA, from either senescent cultures or long-lived mutants. This contradicts the results of Wright and Cummings[4], who interpreted their hybridization experiments, for senescent cultures as well as for *mex1*, as positive. Two hypotheses can be proposed to explain these discrepancies: (1) the nuclear DNA from the subclones studied by Wright and Cummings contains mitochondrial sequences whereas the nuclear DNA from the subclones we have tested does not; and (2) whichever subclones studied, the nuclear DNA has no similarity with the α-mitochondrial sequence, the additional controls included in our experiments explaining their results as being caused by contamination by DNA from mitochondria or plasmids. In the absence of sequencing data demonstrating that a nuclear DNA actually flanks the α sequence, we favour the second hypothesis.

Our data show that a transposition of α sequence to the nucleus is not systematically associated with the senescence process and therefore cannot explain the arrest of growth in *Podospora*. This conclusion is also consistent with the genetic data[18] collected previously which shows that the senescent state is maternally inherited.

I thank L. Belcour and C. Vierny for help and advice, J. Beisson and L. Sperling for critical reading of the manuscript; A. Sainsard and O. Begel for help; and Y. Brygoo and R. Debuchy for the gift of the plasmid containing the *su4* nuclear gene of *Podospora*. I acknowledge the receipt of an ADRC fellowship. This work was supported by a grant from the Centre National de la Recherche Scientifique (ATP Microbiologie).

Thermal erosion by komatiites at Kambalda

GROVES *et al.*[1] have added a further twist to the continuing debate on thermal erosion by komatiite magma. This concept was introduced by Huppert *et al.*[2,3] who argue that hot, low-viscosity komatiite lava flows turbulently and transmits heat efficiently to floor rocks. When the flow rate is high enough and flowage continues long enough, floor rocks melt and are assimilated by the komatiite.

Groves *et al.*[1] present geological observations supporting thermal erosion, but claim the process operates only when a sulphide layer lies at the base of a flow between komatiite lava and floor rocks. They suggest that the sulphide transports heat from the komatiite to the substrate because of its high thermal conductivity, thereby promoting melting. I believe this concept is implausible on fluid dynamic grounds, and that some of the geological observations of Groves *et al.*[1] are open to alternative interpretation.

Figure 1*a* shows the temperature distribution in turbulently-flowing komatiite lava. The temperature remains constant nearly to the lower contact with the country rock, and decreases only in a thin boundary layer. Heat from the 1600 °C komatiite is transported directly to the floor rocks, causing them to melt. The effect of interposing a layer of any other material between the komatiite and the country rock substrate (Fig. 1*b*), even a layer of highly conductive sulphide, is to decrease the rate of heat transport, and to diminish the likelihood of melting. Using parameters listed by Huppert and Sparks[3], and assuming a conductivity for molten sulphide of 10 $\text{W m}^{-1}\text{ K}^{-1}$, I calculate that a 1 m thick sulphide layer decreases heat flux by around two orders of magnitude, if heat transport is solely by convection. Since the sulphide layer is heated from above, thermal convection is unimportant; if flowing komatiite stirs the sulphide, its insulating effect is diminished, but not eliminated.

The apparent association between erosion features and sulphide[1] may result because dense, highly fluid sulphide would naturally accumulate in depressions in the base of the flow, including any formed by thermal erosion.

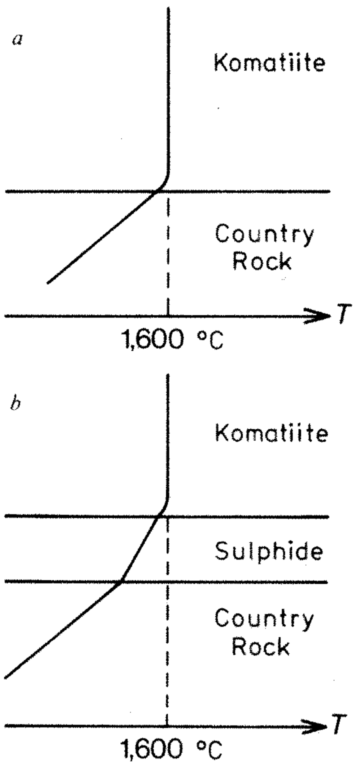

Fig. 1 *a*, Temperature (*T*) distribution in a komatiite flow and underlying rock and *b*, the insulating effect of an intervening sulphide layer.

The komatiite flows envisaged by Groves *et al.*[1] are not lethargic, merely capricious. These authors present convincing evidence that the second komatiite flow in the Kambalda sequence eroded 1 m from the top of the first komatiite flow. For komatiite to be eroded, it must be heated to 1400-1500 °C. Only then is it sufficiently molten to be removed by overriding lava. A lava flow capable of eroding komatiite would erode basalt (which melts at 1200 °C) three times faster, and sediment (which melts at 900 °C) seven times faster[2]. The lowermost komatiite flow at Kambalda, which is thicker and probably more magnesian than its successor[4], should have been capable of producing deep troughs in its basaltic and sedimentary substrate, not merely "second-order irregularities"[1].

Most of the geological features that lead Groves *et al.*[1] to reject the idea of extensive thermal erosion can be explained if we remember that volcanic eruptions are not continuous and that lava does not always follow the same course, but meanders, dams up, and spills out in different directions as the eruption rate fluctuates. Normally eruption rate climbs to a maximum, then declines. At some stage during the decline, the komatiite becomes incapable of erosion. Note also that erosion is not instantaneous but proceeds at a finite rate. Preservation of sediment beneath a komatiite flow may therefore indicate that erosion ceased because the flow rate declined, or the course of the komatiite lava changed. Erupting komatiite initially follows pre-existing valleys, and some primary topographic control is likely. The komatiite flow deepens these valleys, and flowage is concentrated in central feeder channels; a contrast in texture and composition between feeders and flanking units is to be expected. When komatiite encounters a permeable, water-saturated horizon such as flow-top or pillow breccia, hydrothermal circulation removes heat from the komatiite, and the erosion rate decreases. There is an enhanced probability of erosion ceasing when the komatiite reaches a permeable water saturated horizon, and this may appear to be caused by stratigraphic control.

Thermal erosion by komatiite flows is a new concept which may explain some of the geological and chemical features of komatiites that have puzzled us in the past. The task now is to return to mines like Kambalda, or to other areas where komatiites are well exposed to collect new petrologic and chemical data, and to use this information to test the concept. Groves *et al.*[1] have done this in their investigation of interspinifex sulphides, but other aspects of Kambalda geology seem open to alternative interpretation.

How to give good dogs bad names

The British nuclear industry has been given a year to clean up its leaky separation plant, but it will take longer to repair the damage the leaks have done to the reputation of nuclear power.

THERE is nothing quite like the nuclear industry for fossilizing the technology of the past. A nuclear installation, once commissioned, becomes radioactive and thus inaccessible by people, with the result that radical improvements of performance are virtually impossible. This simple truth lies at the root of last week's fierce criticism, by Britain's Nuclear Installations Inspectorate, of the reprocessing plant at Windscale (now called Sellafield) in Cumbria, on the north-east seaboard of England (see p. 603). The plant was designed in a hurry nearly 40 years ago, soon after Britain decided to use plutonium for nuclear bombs. The plant reprocessing the bulk of spent nuclear fuel from British nuclear reactors was built nearly 30 years ago, and afterwards extended in bits and pieces. Throughout the life of the plant, heroic efforts have been made to keep it working safely and sucessfully, but they have not prevented a long string of embarrassing mishaps that would have seemed comic were they not also potentially tragic. Now the nuclear inspectors have rightly said that this must stop, and the Health and Safety Executive has used its legal powers to tell British Nuclear Fuels (BNFL), the publicly owned company that operates the plant, that it has a year in which to put its house in order. "High time, too", will be the general reaction.

So it is, but for a variety of reasons not all as simple as the evident and understandable exasperation of the nuclear inspectors' report suggests. It goes without saying that the mishaps of technical incompetence belie the now-forgotten boast of British nuclear engineers in the 1950s that their techniques would set standards of excellence which, when followed by the rest of British industry, would turn Britain into a temple of high technology. At worst, while accidental leaks of radioactive materials continue, fears will persist that some future mishap will expose large numbers of people to potentially damaging doses of radiation. So it is also proper to acknowledge that, so far, the Sellafield reprocessing plant has not been a significant hazard to public life and health. In part, the reputation of the plant has been sullied by its proximity to the Windscale plutonium-producing reactor, where a fire in 1957 caused the world's most serious release of artificial radioactivity until the Chernobyl accident on 26 April this year. By comparison, the effects of Sellafield's string of mishaps are trivially unimportant.

Safety

Britain's nuclear inspectors conclude that a plant whose safety should be unquestioned cannot be allowed regularly to advertise its frailty. But may not the cumulative effect of Windscale's transgressions be more serious? That is the question that environmentalists are forever asking. There are three respects in which the question is apt and deserves a patient answer. The government of the Republic of Ireland is probably right to complain that the Irish Sea is more heavily contaminated with radioactivity than any other stretch of the world's continental shelves, but BNFL is probably also right to say that the contamination of human food chains is within acceptable limits; even though the discharge is now to stop, continued monitoring will be needed for decades to come. The occurrence of clusters of childhood leukaemia in villages near the plant is another puzzle; a report by Sir Douglas Black two years ago may have correctly concluded than the clusters could be statistical fluctuations, but a diligent search for more immediate causes is plainly necessary. Finally, while Sellafield has a good record of keeping individual workers' radiation doses within statutory limits, the annual collective dose to Sellafield workers is uncomfortably large.

What else is there to complain about? The inspectors inevitably and, up to a point, fairly direct their chief criticisms at BNFL and its managers at Sellafield. But this is where the complications begin. In the old days the operators of the plant enjoyed a reputation for needless secrecy excused, but never fully justified, by the uses to which their chief product, plutonium, may be put. They were also in those days complacent, believing themselves to be fully in charge of a technically advanced plant (which was also true). But the inspectors underestimate the traumatic effects of the period, in the early 1970s, when the stuffing was knocked out of the British nuclear industry by the coincidence of several misfortunes, chiefly government disenchantment with nuclear power (born of the penury in which British governments have rubbed along ever since, but strengthened by the industry's over-optimism about its then new advanced gas-cooled reactor) and growing public hostility. The most damaging complaint in the report is that the present managers at Sellafield have taken to substituting formal approvals by advisory committees for their own judgements, thereby giving bureaucratic processes precedence over practical solutions for real problems. The old arrogance has given way to timorousness, no better suited to the operation of a potentially dangerous plant.

Future

In the present demoralized state of British public life in which nothing much is thought possible, the prospects are not bright for the year that BNFL has been given in which to put Sellafield in order. No doubt the company can fire a few managers and hire some others, but there is little hope of being able physically to rid Sellafield of its huge inventories of unwanted fission products and contaminated material until another public agency called NIREX (Nuclear Industry Radioactive Waste Executive) can negotiate a few sites at which waste materials might be safely stored. BNFL plans to start vitrifying highly active wastes roughly a year from now, but has nowhere other than Sellafield to house the products. And some of the unused facilities that clutter the overcrowded site cannot be dismantled because they are safer as intact relics than if they were broken into smaller pieces. Can NIREX, after five years of failing to find disposal sites, work magic in time to let BNFL complete its assignment?

The inspectors also complain that BNFL has been concerned with the short-term tactics of survival to the exclusion of strategic planning, which may be another consequence of Sellafield's recurring mishaps: BNFL's board members have been made into public relations men (which is not usually their talent). But much of the trouble is external to the British nuclear industry. In 1975, when BNFL had planned a new uranium oxide reprocessing plant at overcrowded Sellafield, it believed it could not follow the sensible course of putting the plant on a second site for fear of a bruising public inquiry and, possibly, refusal. Ironically, it was forced to suffer the inquiry anyway. In present circumstances, the radical strategy of abandoning the old reprocessing plant, replacing it with another, might be safer and even cheaper, but the political obstacles to such a course would be formidable if not insurmountable.

So who is really to blame? The oscillation of successive British governments' policies on nuclear power are largely responsible for the lack of timely investment at Sellafield. The present government, while mildly supportive of nuclear energy in the sense of being prepared to back plans for building new reactors has shrunk from its more onerous responsibility, that of winning by persuasion a civilized accommodation with those dissenting from its own policies, which is the hallmark of good government. But what government would take up cudgels on behalf of an organization as accident-prone as BNFL's Sellafield? In the long run, BNFL's most serious failing may be none of those listed by the inspectors last week, but that of having provided the means by which British nuclear power has been made a formal political issue, with the Labour opposition party committed to the 'phasing out' of nuclear energy. □

Slogans for recovery

The United States must improve its industrial performance in its schools and colleges.

If the Iranian arms scandal blows over soon, some attention may be given in Washington to the emergent slogan of competitiveness, the means by which the US government and its advisers are seeking to accelerate the changing pattern of trade between the United States and the rest of the world. The motives are clear and even admirable. In spite of the devaluation of the US dollar relative to the yen and the deutschemark during the past year, the US trade deficit has not shrunk but, rather, grown to a larger amount than ever, $37,700 million in the quarter ending in September, nearly 6 per cent more than in the previous three months. Although the volume of imports to the United States has indeed shrunk, higher prices (in dollars) of imported goods have kept the trade deficit growing. So it makes sense that the authorities should urge US industry to be more competitive.

Will the new bout of exhortation be more effective than the great fuss about declining US productivity three years ago? There are some obvious snags. In the fields in which US pride has recently been most humbled, motor cars and microchips, there is no reason to believe that US manufacturers invest less in capital equipment and automation than their more successful Japanese competitors. Nor is the United States short of the capacity for engineering innovation. The defects are more subtle — and thus will take longer to repair. The history of General Motors in the past few months is an illustration of how the managements of corporations can become detached from the products they make and from their ultimate customers. And while most of the new ground in microcircuit design has been broken by US companies, the constant worry about quality (or reproducibility) owes much to the shortage of skill on the production lines. Then the development of new products in typical US corporations has been bureaucratized to a degree that must delight the Japanese.

This is why the grave committees now being assembled to brood about competitiveness are certain to conclude that one ingredient of any long-term cure must be a means of persuading many more skilled people into manufacturing industry. Countries such as Britain have long sought solutions to this problem, but without success so far. But even if everybody knows what needs to be done, and has the will to do it, radical improvements of the educational system take decades, not months. Yet the only short-term solutions are crude and unpalatable — reductions of lving standards. That is what the accumulations of trade deficits will, in the end, dictate. □

Solstitial considerations

The disappointments of 1986 have been balanced by good tidings of many kinds.

Before readers of this and other periodicals lapse into the torpor of what seems increasingly to be an international holiday, with elevator muzak playing Christmas carols even in Japan, 1986 should not be mistaken for an entirely disappointing year. True, many of the disappointments have been cruel — Chernobyl, for example. AIDS came to seem more serious a threat to public health than had been thought. The summit meeting meant merely as a preparation for a summit raised peoples' hopes for arms control and then dashed them. The pace of economic growth has been disappointing, especially after the fall of the price of oil (which now seems to be on the way up again). Most countries in the West became more despondent about the difficulties of sufficiently educating the young. There was more than the usual harvest of discovered scientific fraud. Although Orlov was able to leave his Siberian labour camp, his comrade Anatoli Marchenko died in prison only a week ago. The apparatus of the US presidency has once again behaved as if above the law, and seems prepared to trade for hostages as well.

If the good news is, as always, harder to find; it is not less important on that account. People make their own tunes when whistling to keep up their spirits; for some, it is sufficient that there has been no final cataclysm, but that is too little to ask of a dead year, especially one in which there were cheerful signs of beneficial developments. Researchers, pilloried as they often are as denizens of ivory towers, may take particular pride at the speed at which some laboratory studies have been turned to practical ends. Chernobyl, for example, was heroically contained and has been understood. The fear that a large proportion of those infected by the AIDS virus may develop the disease has been partly offset by the hope that some kind of prophylaxis will emerge from the energetic attempts to develop a vaccine.

When it seems that changes of atmospheric ozone in the Antarctic spring may be sensitive indicators of anthropogenic threats to the ozone layer as a whole, the US Navy and the National Science Foundation are able to carry out speedy measurements, suggesting that growing fears of global change may at least be matched by improvements of monitoring capacity (and of understanding). Parallel computers have at last come of age (or will do so when programs have been written for them) while there is new generation of semiconductor devices, formed from GaAs by epitaxial growth, waiting in the wings.

In basic science, 1986 has been distinguished by its ingenuity, typified by the scanning electron microscope (which belongs to an earlier year, but whose inventors were awarded a Nobel prize in that now finishing). The argument (which may be wrong) that a 60-year-old set of gravity measurements contains evidence of a previously unknown force, in the same vein, only helps to show what should never have been forgotten, that the big battalions manning the accelerators do not have all the ammunition. The quasi-crystal saga has provoked many new lines of inquiry into the true structure of solids, while chemists must seriously think again about the electronic structure of molecules with conjugated bonds. The *in vitro* manipulation of plant and animal genes by people is now exquisitely delicate, but the real-life manipulation of genes by protein regulators has begun to be understood. It is no surprise that all this (and much more) should have happened in an otherwise unspectacular year; the surprise is merely that it has happened at a time when budgets have generally been cut, which may say something important about the response of researchers to adversity. The pity is that all this excitement has not been adequately communicated to those who ultimately, through taxes, pay the bills, as well as to their children. For 1986 seems also to have been the year for realizing that too few young people are being adequately trained to keep all these torches alight. □

Nuclear reprocessing

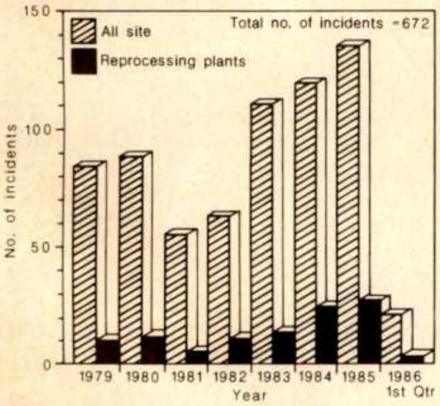
Sellafield threatened with closure within a year

THE management of Britain's only nuclear reprocessing plant, at Sellafield in Cumbria, has been given a year to improve the safety of the site or face closure.

The stern warning has been issued by the Health and Safety Executive (HSE), the licensing authority for the site, after an audit which it describes as "one of the most thoroughgoing physical examinations ever carried out in the UK at one time on any complex plant". The management of the complex, now operated by British Nuclear Fuels Limited (BNFL), is under no illusions about the seriousness of the findings, says HSE.

According to Mr John Rimington, HSE's director general, last week: "Our findings are not recommendations; they will have to be implemented. They match the comprehensive nature of the review. We intend that they should be carried out without delay".

HSE says that the BNFL management has attempted to improve the safety of the processing plant, which is on the site of Britain's oldest nuclear power station. But since 1979, there have been 672 'incidents' at Sellafield. The improvements have not been enough, concludes HSE. According to Rimington: "The main policies and priorities pursued by BNFL in improving the plant seem to us to have been the right ones. But the application of these priorities has reduced the attention paid to potentially hazardous parts of the older plant. Some of these do not yet come up to the scrupulously high standard we demand of the nuclear industry."



One of the most 'hazardous' parts of the plant worrying HSE is the central area/building which performs the initial reprocessing, B205. The executive intends to put political pressure on BNFL to conform and Sellafield's operating licence will be amended to ensure that the improvements are implemented.

HSE gave particular attention to the five incidents this year which caused disquiet and, in part, provoked the audit:

- 23/24 January — discharge of uranium into the sea;
- 5 February — leak from the central reprocessing complex B205;
- 13 February — fire on site;
- 18 February — pipe leak;
- 1 March — spillage of plutonium fuel pellets and subsequent contamination of contact surfaces.

The reprocessing complex at Sellafield is the home for more than 90 per cent of the radioactive waste produced by non-military power generation in the past 30 years. There are 16 reactors in 11 Magnox nuclear power stations in the United Kingdom. The uranium fuel rods of these reactors, enclosed in magnesium alloy containers or cans (Magnox), are stored in cooling ponds at the power stations before transportation to Sellafield; both rods and containers are subject to corrosion.

The chemical separation of the re-usable elements of uranium and plutonium leaves high-level radioactive waste that is stored on site. HSE concluded that as long as this waste remains in liquid form, it can leak and "presents a hazard to those who work there, and potentially to the public or the environment". Less active low-level waste is discharged into the sea or atmosphere or is buried at the Drigg site nearby. **Bill Johnstone**

Chernobyl

Polish fallout underestimated

POLAND's official report on the Chernobyl disaster, published in a limited edition a few weeks ago, makes no mention of the consistent under-reporting of radioactive iodine contamination during the first few weeks after the accident. Nor has the International Atomic Energy Agency (IAEA) or the World Health Organization (WHO) been notified of the error, which is therefore perpetuated by the fallout maps produced by those organizations. The story has, however, been reported by several underground bulletins, notably Wokopach, the newsletter of pro-Solidarity nuclear scientists. The initial error was a genuine one. The emergency on 29 April, was originally set up in the 1960s to deal with the aftermath of a possible nuclear war, and its outdated procedures for iodine estimation systematically lost up to 75 per cent of the iodine before a reading was obtained. Normally, only a few of the 150 monitoring points operated by the public health service are working at any one time, and as the radio-iodine level was normally close to zero, the procedural error was not observed.

Early in May, scientists carrying out independent tests of fallout noted that their readings were consistently 3–4 times higher than the official figures notified to IAEA. The only exception was the official reading from Katowice, where the public health scientists had access to a new, sophisticated estimation apparatus from the United States. At the end of May, the public health network notified the error to the special commission dealing with the effects of Chernobyl in Poland.

On learning of the error, the commission decided not to make it public. It justified this decision to its scientific consultants by pointing out that, a month after the accident, the worst danger from radioactive iodine was over (at that time, the commission did not know that emissions from Chernobyl had continued until 6 May), and that to reveal the error would spread unnecessary public alarm. The danger-level for milk had been set at 1,000 Bq, corresponding, at worst, to a true value of 4,000 Bq — and the level set for Vienna was 5,000 Bq.

Whether the commission was justified in keeping the information from the Polish public is a moot point. Withholding the information from IAEA and WHO, however, is much less excusable as both these bodies would surely have appreciated the commission's evident embarassment over the error and the fear that its revelation might cause panic. Even less understandable is that the story of the error was suppressed in the official report, a publication for official distribution only. *Nature's* attention was first drawn to the matter by a government press spokesman, Mr Jerzy Urban. **Vera Rich**

European Communities

Framework programme in limbo

DESPITE arguing until 4 a.m. on Wednesday last week, Europe's science ministers have failed to agree on a budget for the European Commission's 'framework' programme of research and development, a programme that aims to lay the basis for European cooperation in key areas of research and technology up to 1991. The ministers decided only one thing; to postpone a decision on financing until 22 December, when they will meet again in the hope of completing a compromise which began to emerge in the small hours last Wednesday.

However, the new deal, which involves a three-year rather than five-year programme, has a long way to go before it can form the basis of an agreement. The Commission had tabled a 7,735-million-ECU (£5,400-million), five-year programme, but last week the British, French and West German delegations were sticking on low figures of 3,500–4,000 million ECU, the Dutch on 6,000 million and the other eight delegations on the full amount proposed by the Commission. The gap between the extremes was thus more than a factor of two, and it was difficult to see last week how it could be bridged by the Commission's compromise proposal, of 3,700 million ECU to be committed, and 3,100 million ECU to be spent. These sums would cover three years not five.

Also against the new proposal is the European Parliament, whose energy, research and technology committee has condemned any reduction in the programme, and urged the Commission to prepare to withdraw the whole proposal. Jacques Delors, the president of the Commission, in reply to an address by the British Prime Minister, Mrs Margaret Thatcher to the parliament in Strasbourg last Tuesday, warned that he had instructed research commissioner Karl-Heinz Narjes to abandon the framework programme if ministers failed to give it a reasonable level of financing. Thatcher had just addressed the parliamentarians on the six months of British leadership of the European Communities (as president of the decision-making Council of Ministers) without making any serious mention of research. Delors gives the framework programme a high priority, and was clearly angered that Thatcher had proved an obstacle to its implementation. However, within a few hours, Narjes was proposing the new compromise. Parliamentarians have since expressed their dismay at this outcome, and are pressing for a thoroughgoing confrontation between the Commission and the Council of Ministers.

Finally, however, it may be a smaller straw that breaks the Commission's back: the matter of a 12.6-million ECU increase in the 700-million-ECU four-year budget of the Joint Research Centre's, the group of four laboratories in Italy (Ispra), West Germany (Karlsruhe), Belgium (Geel) and the Netherlands (Petten) which are wholly funded by the Commission. Last week the research ministers received a critical report on the centres prepared by an independent group of European industrialists, and although the Commission already has plans to travel down the road the industrialists recommended (greater interaction with industry, better management of funds), most ministers were sufficiently confirmed in their negative view of the centres that they refused any increase. The exception was the Italian minister, who benefits from the considerable research employment that the largest of the laboratories, Ispra, provides.

Previously fully in support of the framework programme, the Italian delegation has now linked its support to agreement on the increase for the research centres. This must make considerably less likely the unanimous agreement that is necessary for the framework programme to go forward, and it seems probable, barring a miracle, that the framework programme will limp forward, unagreed, to the next six months' Belgian presidency of the Council of Ministers. This would leave a number of programmes hanging loose, such as ESPRIT in information technology, RACE on the development of Europewide integrated broad-band communications, EURAM on advanced materials and the unstarted joint research programme on AIDS. There is around 1,050 million ECU in the European kitty next year to continue existing programmes, but this is not enough to increase the pace of cooperation intended.

Robert Walgate

Embryo research

UK legislation further delayed

STILL wriggling uncomfortably on the hook of human embryo research, the UK government last week issued a consultation paper on *Legislation on Human Infertility Services and Embryo Research* (Cm 46, HMSO, £2.90), asking for responses by the middle of 1987. The aim is then to introduce legislation, although it seems likely that a general election will intervene.

The paper is based on the Warnock report, published in 1984, since when the government has avoided three attempts by members of parliament (MPs) to prohibit almost all human embryo research, while promising its own legislation. From these attempts and other responses, the paper divides Warnock's recommendations into those where "a broad measure of agreement is likely" and those where it is not.

Chief among the contentious issues, according to the paper, is the use of human embryos for research purposes. One camp argues that research is both necessary and warranted. It is necessary to improve infertility treatments, contraceptive techniques and the detection of early abnormalities. And it is warranted for 14 days after fertilization. The other camp is opposed to any research that leads to the destruction of an embryo because this "is tantamount to murder", says the paper.

Pointing out that even the members of the Warnock committee were split on this issue — as are government ministers — and that various intermediate positions have been expressed, the paper says that the government intends to offer parliament alternative sets of draft clauses dealing with the issue, and to allow MPs to vote according to their consciences rather than along party political lines.

Other issues that are considered contentious are the possibility of egg or embryo donation and whether human sperm should ever be allowed to fertilize animal eggs, even as a test for sperm quality with destruction of the embryo after one division.

Although commercial surrogacy was made illegal in 1985, the paper invited comment on whether the law should be amended to allow the surrogate mother and the commissioning parents to be prosecuted. It also seeks views on the possibility of a non-commercial surrogacy service.

Only one reaction to the consultation paper is unanimous, namely that it is a delaying tactic. Mrs Phyllis Bowman, director of the Society for the Protection of Unborn Children, says the paper is nothing but a rehash of the Warnock report. A spokeswoman for Progress, a lobbying group in favour of human embryo research agrees but sees the delay swinging public opinion in the group's favour.

The last attempt to prohibit human embryo research was on 13 October when Mr Ken Hargreaves MP introduced legislation in a way that stood no chance of being accepted but at least forced a vote. As on past occasions there was a substantial, if reduced, majority in favour of the proposed bill. Meanwhile, such research continues under the auspices of the Voluntary Licensing Authority set up last year by the Medical Research Council and the Royal College of Obstetricians and Gynaecologists. The authority tends to follow the recommendations of the Warnock report, which are sometimes more liberal than local ethics committees through which medical research proposals have also to pass.

Peter Newmark

Medical research

Backs to the wall in Britain

The British Medical Research Council (MRC) faces a deficit of £13.2 million by the end of the decade even if it does no more than maintain the existing rate of awards and renew long-term grants at an appropriate level. But there is also a pressing need to spend more on research into AIDS (acquired immune deficiency syndrome) and to offer more competitive salaries to keep the best scientists, says Sir James Gowans, secretary of MRC.

Introducing the council's annual report in the year before he retires, Gowans described AIDS as a "national emergency" that deserves special earmarked research funds. Discussions with government departments seem likely to produce the £0.5 million needed immediately for one major and two minor AIDS projects, but several million pounds will be needed over the next few years. (A bare £2 million was spent on AIDS research by MRC and the Department of Health and Social Services in the past year compared with the $40 million predicted for 1987 in the United States.) Priority must be given to monitoring the spread of the virus that causes AIDS and the effect of the campaign to reduce the spread, said Dr D. A. J. Tyrrell, chairman of the MRC working party on AIDS. But neither he nor Gowans would be drawn on how to overcome the problems that are holding up monitoring (see *Nature* **324,** 396; 1986).

On salaries, Gowans expressed frustration that MRC's grant-in-aid, worth £129 million last year, assumes an increase of only 3 per cent this year and 2.5 per cent next year when pay awards are running at 5–6 per cent. The level of awards for its staff is not controlled by MRC as it is tied to increases for their university, clinical and civil service equivalents. That, and the decreasing budget, also constrains the ability of MRC to offer salaries that compete with offers from industry and overseas. At the top level, however, the council is free to offer more competitive salaries as long as the mean is maintained at the average for professors in universities, which have the same flexibility.

Unless the MRC budget is increased, said Gowans, it will be extremely difficult for the council to grasp new opportunities in research. The problem is already very serious; 90 project grants were approved but not funded in the past financial year. Royalty income from discoveries made by MRC scientists is expected to increase in coming years, particularly through the activities of the new Centre for Collaborative Research. But last year it was only £0.1 million and a limit of £2.5 million has been imposed. **Peter Newmark**

Japanese volcanoes

Forecasters wise after the event

Tokyo

Japan's Volcanic Prediction Liaison Council seems to have been rewarded for its failure to forecast the behaviour of Mount Mihara on Oshima, the volcanic island south of Tokyo evacuated during a major eruption last month. The council has won substantial new facilities on the island that will make Mihara one of the best-monitored volcanoes in the world.

The council, advisor to the Meteorological Agency, has come under fire for its pronouncements about Mount Mihara. At the end of October, following the outbreak of volcanic tremors, the council declared that any eruption would be "several months or years" away. Even when the lava started spewing out of the volcano two weeks later, it was confidently predicted that the flows would be confined to the caldera. But when a new line of vents broke through the caldera rim, sending lava surging towards the main town Motomachi, and the island had to be evacuated, the council turned about and started issuing warnings that mixing of sea water and magma could lead to a phreatomagmatic eruption, as at Krakatoa.

The Mount Mihara eruption at its peak on the night of 21 November.

Now, almost a month later, with the volcano silent and the government running up huge bills to support the evacuees, the council has been under pressure to issue an all-clear. Finally, last Friday, its members adopted a "unified view" that Mount Mihara is now calm "in the short term"; the Tokyo Metropolitan Government immediately announced that the islanders would be allowed to return to Oshima between 18 and 22 December. But the council's decision was given on the precondition that the island's volcano-monitoring network be substantially upgraded before the islanders return.

The number of seismometers on the island will be almost doubled, to nineteen. Seventeen new tiltmeters will be put in place along with various other pieces of equipment costing a total of Y1,100 million (£5 million). The seismometers will be linked to telephone lines and 40 engineers of Nippon Telephone and Telegraph are racing to link the seismometers to a telemetric network by 19 December.

Preliminary analysis of the November data suggests that prediction will still be unreliable, and that details will often be discovered only after the event. Seismograph data did, however, play an important role in the evacuation, according to Professor Aramaki of Tokyo University Earthquake Research Institute, who spent the night of 21 November at a police station in Motomachi. A shift in the earthquake swarms to a position off the south-east coast of Oshima, reported by telephone to Aramaki by researchers at Tokyo University's observatory on the island, coincided with police reports of new cracks in a road near Habu, the south-east port of Oshima; acting under Aramaki's advice, police removed evacuees from Habu to the northern ports of the island.

The new equipment will be operated by Tokyo University and the Meteorological Agency as well as various other government agencies. But it remains to be seen whether they can work together. While Tokyo University researchers stuck to their posts on 21 November, as a river of lava bore down on their observatory, officials of the nearby Meteorological Agency Observatory were among the first to flee the island. Feelings between the two groups are strained. **David Swinbanks**

Pesticides

FDA told to try harder

Washington

THE US authorities are not doing enough to catch and prosecute unscrupulous food growers who may be steadily poisoning the American public through illicit use of pesticides. A study* by the General Accounting Office (GAO) concludes that the US Food and Drug Administration (FDA) is the agency most at fault.

The study shows that the proportion of tested domestically produced food is small (probably less than one per cent), and, more significantly, that over half of pesticides that may be present are not detected by any of FDA's five preferred 'multi-residue' tests. Eight out of the nine most dangerous pesticides used are not detected by these standard tests. The agency uses the more time-consuming and expensive single-residue tests only when it has reason to suspect chicanery.

The proportion of tested samples has fluctuated since 1979 between 1.8 and 4.5 per cent, but more than 5 per cent of fish samples tested over the same period contained illegal residues. FDA says these proportions are not representative of the food supply as a whole, as trouble spots are sampled more often.

But the most disturbing discovery of the report is FDA's record at preventing the sale of adulterated food and prosecuting wrongdoers. In 107 out of 179 cases in which the agency found illegal residues (over a period of more than two years), the food had already been sold by the time the result came through, and in none of the 179 cases did FDA seek criminal penalties. Because the agency lacks detention authority over domestic food, it often cannot prevent such food being exported —but it can seize adulterated imports.

FDA also lacks legal authority to impose civil penalties, a shortcoming GAO would like remedied to provide an effective deterrent. The alternative, costly criminal procedures, is rarely used. Congress may hold hearings on the agency's effectiveness at pesticide control next year, and should be interested in the idea.

Does all this mean that Americans are being poisoned? Not quite. Illegal residues may simply be pesticides applied to the wrong crop, or may exceed approved 'tolerances' by a small amount. The tolerances are supposed to have large built-in safety margins. Environmental groups say, however, that the factor of 10 sometimes used in extrapolating safe dosages from animal studies is inadequate and that tolerances are set before all the relevant data are collated. **Tim Beardsley**

Pesticides: Need to enhance FDA's ability to protect the public from illegal residues. (GAO, 1986).

UK industrial research

More stick than carrot on offer

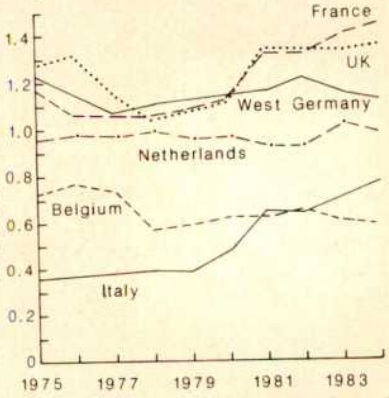
BRITISH manufacturing industry, part of which enjoys lucrative defence contracts, must itself spend more on research and development, says Mr John Fairclough, the government's chief scientific adviser.

Annual government investment in research and development is £4,300 million, of which 51 per cent is channelled into the Ministry of Defence (MOD). In sharp contrast, the Department of Trade and Industry (DTI), one of the principal sources of industrial research funds, has seen its share fall from 7.9 per cent of the pool in 1983–84 to an estimated 5.2 per cent in 1988–89.

The call for more investment came on the publication of the government's review of research and development expenditure. Although Britain invests more in publicly funded research and development than most of its European neighbours, but as a proportion of Gross Domestic Product, the total devoted to civil projects lags behind West Germany, France, Japan and the United States.

Fairclough, who began a two-year secondment from IBM (UK) to the Cabinet Office in May, is attempting to change that ratio. One solution is for companies publicly to disclose their research and development expenditure. Such disclosure, Fairclough believes, would make financiers aware of the long-term strategies being adopted by companies.

The Fairclough solution was not the only one to emerge from Whitehall last week as the government attempted to forge better links between its departments, the universities and industry.



Another, credited to the Prime Minister, Mrs Margaret Thatcher, is a programme for re-routing £210 million of the budget for scientific research and development to "speed up the development of products and services from scientific and technological research carried out by universities, government departments and industry".

The programme, called LINK, is to encourage research and development partnerships between the scientific community and industry. Government funding is spread over five years and is expected to attract the same from industry.

Mrs Thatcher, in announcing the programme, said that "the excellence of British science has not been matched by a rapid pace of application by British industry of the newly emerging technologies. Nor is the private sector investing as much of its own resources in research and development in this country as are our more successful competitors."

Fairclough — more for research.

The success of the LINK programme will require cooperation between government departments which in the past have been noted for their rivalry. They are the departments that already have research budgets — the Departments of Trade and Industry, Education and Science, Energy, Environment, Transport, Health and Social Security, Agriculture Fisheries and Food and the Ministry of Defence. The Scottish, Welsh and Northern Ireland offices will also be involved.

There will be a steering committee composed of senior industrialists, academics and officials from the relevant departments and research councils with a brief to foster strategic areas of scientific research directed towards "the development of innovative products, processes and services by industry"; to stimulate industry to increase its investment in research and development; to encourage industry to exploit developments in science; to make scientists more aware of the needs of industry; and to develop technologies that cross the normal boundaries of scientific disciplines.

The Advisory Council for Applied Research and Development, the Advisory Board for the Research Councils, the Assessment Office on Science and Technology in the Cabinet Office are collaborating to find other ways of marrying research to industry. **Bill Johnstone**

Nuclear safety

United States opts for caution

Washington

The principal US military plutonium production reactor, a graphite-moderated plant similar to that at Chernobyl, is to be shut down for six months by the Department of Energy (DoE) to carry out urgent safety modifications which could cost about $50 million.

N reactor at Hanford site.

The 23-year-old 'N' reactor on the Hanford military nuclear reservation in Washington state has been a focus of concern since the Chernobyl accident. Besides being graphite-moderated, like Chernobyl-4 it lacks a containment structure capable of withstanding steam and hydrogen explosions that might occur in an accident. Two out of six independent consultants, asked by DoE to assess N-reactor safety, recommended closing down the reactor immediately and permanently, unless to do so would threaten national security.

Others said the poor containment meant the consequences of an accident would be worse than at a commercial power station, and that they could support continuing operations only if further safety checks were made. DoE declined the invitation to shut down the reactor permanently, but has accepted the need to spend immediately $50 million on improvements.

The consultants, under Louis H. Roddis, submitted independent reports, agreed that there was virtually no possibility of a Chernobyl-like accident, but found that radioactivity might be released following a minor accident because of doubts about the N reactor's 'confinement' system, which is designed to lower pressure in the reactor building after an accident by spraying cold water. The system has never been tested under realistic conditions. One consultant commented that the list of required improvements is so extensive that a commercial reactor would be required to shut down to carry them out. Management improvements were also urged.

The consultants urgently recommended installing a hydrogen mitigation system, and a 'basin' for collecting radioactive water that would be released in an accident. Hydrogen explosions figured in both the Chernobyl and Three Mile Island accidents, but the N reactor confinement system would not withstand an explosion of the size thought possible, according to the consultants. And under present plans, contaminated water would be temporarily stored in a desert pit, a plan DoE acknowledges to be inadequate. The department says it will start to install a hydrogen mitigation system immediately and also accelerate a comprehensive probablistic risk assessment now in progress.

While announcing the temporary shutdown, DoE also said it was awarding a 5-year, $4,000-million contract to manage the entire Hanford operation to Westinghouse. The N reactor was previously managed for DoE by the General Electric Company, and some of DoE consultants noted "complacency" over safety. Another contractor at Hanford, Rockwell International, has been the focus of allegations of poor management at two plutonium production plants recently shut down temporarily for safety violations.

Whatever safety improvements are made, the N reactor will not be in business for much longer. Commissioned in 1963 with a design lifetime of 20 years, its pile is now expanding at the rate of 0.8 inches per year, putting stress on coolant pipes and threatening to hit the thermal shield in as little as 3 years. That will be the end for the reactor as replacement of the whole pipe is not feasible. DoE is now trying to decide whether it needs another plutonium production reactor (it has others at the Savannah River complex in South Carolina) for next century's nuclear weapons.

Tim Beardsley

Albanian outlook

Changing tack on exports

Ramiz Alia, who became leader of the Albania Workers' Party (AWP) on the death last year of Enver Hoxha, has an unusual approach to his country's nonrenewable natural resources. "The interests of future generations", he told the AWP congress last month, demand that such assets as copper and chromite ores be "put into economic circulation as soon as possible", by extracting and exporting them. "It is better to leave these natural assets to future generations in the form of factories, plants and combines, as means of production, as functioning assets, rather than in the form of potential resources hidden underground", he said.

Although he was referring chiefly to mineral ores, Alia's speech made it clear that Albania's new five-year plan will attempt also to increase its capacity for exporting oil and coal. Albania, the least developed country in Europe, thus differs markedly from most developing countries which see the massive export of raw materials as a vestige of colonialism, and aim instead at the export of finished or semi-finished products with a larger added value. But the policy of Albanian self-sufficiency established by Hoxha after his breaks with the Soviet Union and then with China means that the country must implement its plans for modernization without foreign loans or grants-in-aid.

In these circumstances, Alia's view that future generations can best be served by selling off the country's irreplaceable assets does make some kind of short-term sense. Albania's economy is still based largely on human muscle-power. The 'prestige' civil engineering projects of recent years, such as hydroelectric dams and railways, have largely been built by student volunteers, equipped with little more than pick and shovel. Agriculture is labour-intensive, and Alia's promise to "increase the role of science in its service" will entail not a decrease in the numbers employed but a "considerable increase".

Science in the service of production is one of the main targets of Alia's programme. This policy demands trained personnel, in a country where at present only 57 per cent of young people receive more than primary education. (By 1990, according to the plan, this figure should rise to 73 per cent.) Alia's speech stressed not only the need for more trained scientists and technicians, but also for better management of science. The Albanian Academy of Sciences, he said, must give "more initiative and thought" to the directions in which the sciences should develop, while the Committee for Science and Technology must provide "better planning, a clearer definition of priorities and more effective organization and coordination of manpower and resources". The University of Tirana and other institutions of higher education must become "bodies of consultation for the broad masses of specialists in production", while the ministries concerned must refrain from turning educational and research centres into mere "administrative apparatuses".

In spite of Alia's boast that Albania can now train all the specialists it needs, and in spite of "self-sufficiency", the country is still, of course, largely dependent on foreign scientific achievements. And to enable Albanian scientists and technicians to make use of foreign results, the Ministry of Education has been instructed to remedy the "unsatisfactory situation" in the teaching of foreign languages. **Vera Rich**

Australia

Lay head for CSIRO board

Sydney

THE initial reaction of the Australian scientific community to the appointment of former New South Wales Premier and federal president of the Australian Labour Party (ALP), Mr Neville Wran, as head of Australia's largest research body, the Commonwealth Scientific and Industrial Research Organization (CSIRO), lay somewhere between surprise and shock. The parliamentary opposition described the appointment as "appalling political cronyism". Many CSIRO scientists were dismayed by Wran's appointment, which marks the end of a 60-year tradition of having a scientist at the head of CSIRO, but this feeling seems to have given way to guarded optimism that Wran's undoubted political acumen and extensive connections with industry will be great assets.

Wran was premier of New South Wales for 10 years and federal president of ALP for 6 until his surprise resignation from both positions last July. His government would not have had to face another election until early 1988. The stated reason for his resignation was that he was tired of politics and that stepping out mid-term would give his successor time to get used to the reins of government before having to face an election.

Wran's appointment coincides with the disclosure of legislation designed to give CSIRO a new board and structure. The changes are the result of recommendations by an Australian Science and Technology Council review of the organization's operation. In the new board, policy-making and management functions have been separated to make it more like the board of a normal corporate body. The old board consisted of three full-time members, all distinguished scientists, and five part-time outside members. One of the full-time members was chairman and chief executive, a position held in the last board by Dr Keith Boardman. In the new model these posts have been split, with the chief executive becoming the only full-time member of a 10-man board. The chief executive is thus the most senior CSIRO scientist. Boardman has been appointed permanently as chief executive subject to the approval of the board which is due to meet for the first time this month.

It will be the task of the new board to align CSIRO's research ambitions with national priorities, which means increasing emphasis on industrially applicable research, particularly on that applicable to manufacturing, although Boardman is careful to point out that this does not mean a diminution in either the quantity or quality of fundamental and rural research carried out by CSIRO. In fact, the number of scientists working in rural research has increased because of more funding from outside sources despite the decreases in government money.

In addition to Wran, the part-time board members include two scientists, a farmer, a representative from the union movement and four representatives from industry, so it should be well suited to its task of linking CSIRO to the strategic needs of industry.

The Minister for Science, Mr Barry Jones, has long bemoaned the poor record of scientists for standing up in public and speaking out for their own cause, and has even gone so far as to call them "wimps". Perhaps the appointment of a politician to head CSIRO means that Jones has concluded that the best way to get the scientists' case heard is to give them a voice to speak for them.

Charles Morgan

Britain gets Cray supercomputer at last...

THE UK Science and Engineering Research Council (SERC) has at last taken delivery of its Cray X-MP/48 supercomputer, after much discussion between the British Department of Trade and Industry and the US Department of Commerce.

For months, the latter has been concerned that 'foreign aliens' might gain easy access to the supercomputer which is to be housed at the Rutherford Appleton Laboratory. The Americans wished to impose rigid restrictions on SERC, a move vigorously resisted by the British authorities.

For logistic reasons, trade officials from both sides of the Atlantic had been unable to meet to discuss the subject, so the Americans have approved the purchase to prevent any further delay but without receiving the assurances they originally sought. The trade authorities will meet soon to discuss the 'principles' of the case. The machine will be operational by the end of January and will run by SERC on behalf of the research councils and the universities. SERC says the Cray "will be a considerable boost for UK scientists and engineers engaged in a wide range of computer simulation problems", including the physics of liquids and solids, large-scale-integration circuit design and aircraft design.

The supercomputer has been acquired partly as a result of a report prepared for the Advisory Board for Research Councils, the Computer Board and the University Grants Committee, entitled *Future Facilities for Advanced Research Computing*, by a working party under the chairmanship of Professor John Forty of the University of Stirling, who has agreed to be chairman of the management committee for the supercomputer service.

Bill Johnstone

...and Indian supercomputer is on the way

New Delhi

AFTER protracted negotiations, India and the United States have signed a document paving the way for the sale of a Cray-XMP supercomputer to India. The deal was approved in principle by the US administration eight months ago but became bogged down because of disagreements over the US terms and conditions for its sale. Indian demands that its sovereign rights should not be violated in any arrangement and US fears about possible misuse by India and potential leakage of technology to the Soviet bloc were the bone of contention. The problems were resolved and mutually acceptable conditions of safeguards were finalized last week after three days of intense negotiations between the US delegation led by Assistant Secretary of State Robert Dean and officials of India's External Affairs Ministry. The signing of the safeguards document has cleared the way for India to become the first non-NATO country to receive the computer.

According to a US spokesman, the safeguards are similar to those applicable to US computers sold in Britain and West Germany. The United States, which initially insisted on unrestricted right of inspection to check diversion of technology to third countries, finally agreed to exercise the right only in the event of suspected diversion. It also wanted to station US personnel permenantly at the computer facility, but agreed to the Indian request that US participation should be a temporary arrangement to be reviewed after 2–3 years when Indians would be ready to man the facility on their own.

The supercomputer, which is expected to cost about $20 million, will be installed in New Delhi under the operational control of the Department of Science and Technology. It will be used for meteorology but the United States has agreed to let India use any spare capacity for certain stipulated other areas of research excluding nuclear or defence-related spheres.

The Indo–US deal on the supercomputer is being keenly watched by Japan. As negotiations with the United States were proving difficult, India had six months ago placed orders for three supercomputers from Japan, but the export was stopped under pressure from the United States. Now that the safeguards have been worked out, Japan will have no difficulty in exporting similar computers to India, which hopes to install four of them by next year.

Rabies vaccine

Inquiry into Argentine trials

Washington

OUTRAGE and calls for investigations have followed in the wake of revelations about field trials of a recombinant rabies vaccine conducted by the Pan American Health Organization (PAHO) (see *Nature* **324**, 202, 1986). Both the National Institutes of Health (NIH) and a congressional committee have begun inquiries into the affair, in particular into the role of the Wistar Institute of Philadelphia where the vaccine was made. Although the government of Argentina has made no formal comment on the tests, members of the Argentine scientific community feel the trial was conducted without safety precautions that would have been required had the trial been carried out in the United States (see p. 610). But Hilary Koprowski, director of the Wistar Institute, says people should be rejoicing that the new vaccine seems to be a success and not complaining about an experiment now over.

The new vaccine uses a vaccinia virus genetically engineered to contain an immunogenic gene from a rabies virus. Tests on laboratory and captive animals have shown the vaccine to be successful in inducing antibodies against the rabies virus. A total of 20 cows were vaccinated at the PAHO field station in Azul, 180 miles south of Buenos Aires. Ten cows were vaccinated intramuscularly and ten subcutaneously. Each group was kept in an open paddock with 10 unvaccinated cows.

But the field test, begun in July, was terminated in early fall after a commission of Argentine scientists visited the Azul station and raised questions about the way the experiment was being conducted. The commission reported that there were no signs announcing the nature of the experiment, both wild and domestic animals could come in contact with the vaccinated cows, excreta from the vaccinated animals was not being treated and milk from the vaccinated cows was being consumed by humans and animals at the Azul station. According to Mercedes Weissenbacher, one of the commission members, some of the milk was sent to a local dairy where it was used for making powdered milk and confectionery. Koprowski says the milk should have been frozen and sent to Wistar's French collaborator Rhone-Merieux to be tested for the presence of virus.

PAHO agreed to terminate the experiment after the commission's visit to Azul. Although Koprowski complains that PAHO was prevented from obtaining further blood or tissue samples from the vaccinated animals to see if the vaccine was still effective, Weissenbacher says blood and milk samples were collected before the animals were killed last month and are being stored for analysis.

Koprowski is upset that the animals were killed before they could be challenged with virus. He maintains that initial results were successful, the virus was not shed, neither humans nor animals became sick and the vaccinated cows developed antibodies to rabies virus.

PAHO has declined to answer questions on the trial. Carlyle Guerra de Macedo, director of PAHO, admits "mistakes were made in the way the matter was handled", but says a full disclosure will have to wait until discussions with the Argentine government are concluded.

Jose La Torre, director of the Centro de Virologia Animal and a member of the Commission sent to investigate conditions at Azul, says he agrees that the vaccine trial was an important one, but he objects to the way it was conducted. Weissenbacher concurs, adding animal care workers should not have been involved in the vaccine trial without obtaining permission from Argentine health officials. In justifying performing the experiment in Argentina, a PAHO spokesman said last month that cattle losses from rabies in Argentina amounted to millions of dollars a year. But a spokeswoman for the Argentine embassy in Washington said such losses were closer to $60,000 a year.

La Torre visited Wistar in 1984 along with representatives of the Argentine pharmaceutical company Paul which was interested in trying the new rabies vaccine. Koprowski says Wistar told the Paul representative such a commercial arrangement would have to be made through Transgene, Wistar's French collaborators. Paul never contacted Transgene, but La Torre says that following his visit he wrote to officials at Wistar, informing them that they would need permission from the Ministries of Agriculture and Public Health to conduct a field trial. An Argentine law, adopted in 1903, prohibits the import of exotic viruses into Argentina. Wistar associate director Warren Cheston says a preliminary document from Wistar to Paul concerning a licence for the vaccine charged Paul with responsibility for notifying Argentine officials.

News of the Azul trial reached the Argentine scientific community when Mauricio Seigelchifer, an Argentine scientist visiting Wistar, wrote to colleagues about the experiment. Although Seigelchifer's contract with Wistar ran until the end of the year he returned to Argentina last week.

Joseph Palca

Israel

University shake-up on cards

Rehovot

A MAJOR reconstruction of the higher education system in Israel that would create a two-tier structure, halt the growth in the number of students at existing institutions and raise tuition fees has been proposed by Professor Jacob Ziv, head of the Grants and Allocation Committee of the Council for Higher Education. Ziv, who oversees the allocation of US$246 million a year to the universities, believes there is no alternative if the growing demand for higher education is to be eased.

The universities' share of the national cake has substantially declined in the past decade. In the mid-1970s, they received 7.7 per cent of total government budget allocations (exclusive of defence expenditure and debt repayment), this year it was 4.4 per cent. This reflects a change in priorities, as during the same period government support of education (below university level) and of health services went up by nearly 40 per cent.

There has been a change for the better since the present government took office in 1984, but funds remain short and there is no solution in sight for the debts of $200 million of Israeli institutions of higher education, about half of which are borne by the Hebrew University. They have become so onerous for the university that it delayed opening its school year and its president and director general have resigned.

Although Ziv, formerly dean of electrical engineering and vice president of academic affairs at the Haifa Technion, wants more government support, he also favours restructuring higher education.

His most far-reaching proposal is for a two-tier system to halt the growth of the student population at present undergoing higher education (now increasing by about 3 per cent a year) and perhaps to reduce the numbers. Young people unable to qualify for admission under the new rigid standards would go to two-year study centres, if they did well, they could eventually transfer to a university. These centres would be inexpensive "teaching factories" staffed mainly by part-time lecturers who would not enjoy the conditions or research facilities of university personnel.

A ministerial committee is now studying Ziv's proposal to raise university fees (now about $1,200 a year). But as he sees, it, less affluent students should be allowed to pay their fees after graduation.

University libraries are less well stocked than they used to be, modern equipment is often lacking and salaries are only a quarter of those paid in the United States. The result has been a brain drain and even scientists who retain their posts in Israel often do much of their research overseas.

Nechemia Meyers

Wistar's export to Argentina

SIR—Argentinian scientists have recently been disturbed by an experiment involving both humans and domestic animals infected with a live recombinant vaccine [An account of the experiment appeared in *Nature* (**324**, 202, 1986) after this letter was written]

The experiment was carried out in an experimental farm of the Panamerican Health Organization of Azul, province of Buenos Aires, following a protocol designed by the Wistar Institute of Philadelphia, it was supervised by Dr J Held (director of Centro Panamerico de Zoonosis, CEPANZO, PAHO), Ana Maria Diaz (head of the rabies unit), Elmo de la Vega (chief of pathology) and Luis Lazaro (chief of the Azul Field Station)

The experimental protocol was presented by Dr Roberto Weimann from the Wistar Institute, who flew to Buenos Aires immediately after the nature of the experiment became public, thanks to the action of a group of scientist from AADICYT, the Argentinian Association of Research Scientists Soon after, the Argentinian Ministry of Health appointed a special committee of inquiry After interviewing Weimann and visiting the premises of CEPANZO at Azul, the committee recommended the immediate interruption of the experiment, based on the following evidence

(1) The experiment was started on 1 June 1986, without the permission, consent or notification of any Argentinian human or animal health authority

(2) The effects and eventual risks of the inoculation of a rabies-vaccine recombinant virus in open-field cattle and its possible transmission to humans are completely unknown The only reports in the current scientific literature deal with laboratory animals (mice and rabbits, *Proc natn Acad Sci U S A* **81**, 7194, 1984) and foxes kept in captivity (*Nature* **322**, 373, 1986) There is particular concern about a possible alteration in the tissue localization of the recombinant virus as in the case of the Moloney murine leukaemia virus-rabies recombinant (M P Kriegler and C Perez, Scientific Report 84/85, Institute for Cancer Research, Fox Chase Cancer Center) that might produce long-term consequences difficult at present to assess

(3) There were serious violations of ethical, ecological and safety rules

- The inoculated animals were not kept in isolation, permitting the free access of other wild and domestic animals to the area, with the danger of spreading the new virus in an open ecosystem
- No warning signs were placed at the experiment area
- There were precise instructions that the same two animal handlers should milk each group of cows throughout the experiment
- The four animal handlers were not vaccinated against smallpox before starting the experiment The only sign of previous immunization considered by those responsible for the experiment was the presence of a scar compatible with vaccination
- The four animal handlers were not under medical surveillance
- Some of the milk from the inoculated cows was consumed by the animal handlers and their families without being pasteurized The bulk of the milk was sent to the local market, and distributed to the community after pasteurization
- The way in which this experiment was performed clearly infringes the World Health Organization's recommendations about experience involving recombiant DNA technology (Bethesda, 1984, Geneva, 1985)

We are not against the development of recombinant vaccine technology in view of its potential value for effective disease control But we think that recombinant vaccines, like any other recombinant DNA project involving humans, must be developed in the light of international laws and recommendations, caring ethical and ecological consequences

Moreover, we feel that our country has been illegally used as a test field for a kind of experiment that is not yet accepted in the countries where basic research on this vaccine had originated

Defensive deterrent

SIR—At the time I was approached, I objected to the Cornell survey of National Academy members (*Nature* **324**, 4, 1986) as to the feasibility and desirability of the Strategic Defense Initiative (SDI) even though I agree that no defensive system would be able, within the next 25 years, to provide effective population defence, even if the Soviets froze their arsenals at current levels But as Reykjavik (which took place after the survey was completed) demonstrated, this is not the right question Rather, we should be asking whether, if arms control leads to a mutually agreed reduction in the offensive threat to, say, a few hundred offensive missiles, can a defensive system be effective against this much lower threat? The answer to this question is probably yes, I would guess that many of my fellow academicians who denied the feasibility of a defensive system against the current threat would concede that defence is feasible against a lower offensive threat That those responsible for the Cornell survey did not give the respondents this choice I consider to be an improperly restrictive view of the matter

Indeed, the entire episode reflects a curious bias in the academic world against the so-called defensive-dominated world A defence-dominated world in which peace is maintained by denial of aggressive intent is surely morally superior to the present offence-dominated world in which peace is maintained by threat of mutual genocide — provided the defence-dominated world and the transition thereto can be adequately stable

Rather than sanctifying the current offensive world as being the only one in which peace is maintained, academic peace studies groups ought to be examining in full seriousness the defensive world Reykjavik gives us a glimmer of hope that the first step to a defensive transition — deep reductions in offence — is not a will-o'-the-wisp How to stabilize such reduction by appropriate defensive deployment and how to redirect SDI towards this goal ought to be central elements in academics' peace agenda, much more than ill-considered, and I fear, politically-inspired, attempts to discredit any movement toward a defence-dominated world

South Africa

SIR—Britain took 96 years to get full suffrage, in four stages, the last only 58 years ago During that time, poverty (far greater than that in South Africa today) virtually disappeared, owing to the gradual increase in wealth brought about by entrepreneurs South Africa needs *more* trade and contacts with other countries so that it can continue to raise the average standard of living

The advanced countries demand that South Africa make really major social changes much more quickly than they did, at the same time they apply sanctions that cripple its power to do so Such behaviour may be explained, but not excused, by the campaign against South Africa in the media, especially television, during the past year or so The letter of J A Barnes (*Nature* **324**, 104, 1986) rather dispels the hope that an academic would show more understanding

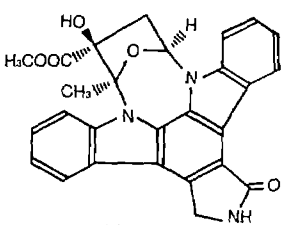
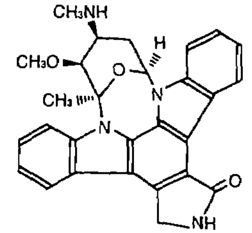
NEW REAGENTS FOR PROTEIN KINASE RESEARCH FROM KYOWA

K-252a and Staurosporine, microbial alkaloides are potent inhibition of protein kinases with Ki of 0 7 ~ 25 nM



K-252a



Staurosporine

* Purity, >99%
* Solubility, Readily soluble in DMSO and DMF
* Stability, Stable at room temperature, store protected from light

THE SOFTWARE DIRECTORY FOR MOLECULAR BIOLOGISTS

Christopher Rawlings

This single volume brings together the scattered information on software available to molecular biologists.

The Software Directory compares and critically appraises specialized software for molecular biology, and also provides you with concise descriptions of commercial and business software applicable to laboratory work

Each entry covers functional features, machine type, computer manufacturer, operating system, and author or company The book also contains a thorough index of all the software listed, under seven different headings (the five above, plus package name and keyword)—so that you can always find the software that is right for your work, quickly and easily

The all-new *Software Directory for Molecular Biologists* gives you accurate information on all known software in the field—commercial or non-commercial You will save time and money with this invaluable guide

PFIZER AWARDS 1986

Pfizer Central Research at Sandwich, Kent announced in October 1982 that they would make up to six new Awards annually to support young scientists who had carried out meritorious research at British Universities or equivalent Institutions The research should have potential application in the search for human or animal health drugs In 1986 each award is £2,000.

The award winners are selected by a panel of Pfizer scientists in consultation with senior academic advisers. They are made on the basis of work published in the previous two years or, in the case of a second consecutive award, in the previous twelve months. No person may receive more than two awards. The awards are for the personal use of the recipients to further their research and are NOT open to application

The 1986 winners are.

Chemistry

1. Professor P. J. Kocienski, Department of Chemistry, University of Southampton.

"For his novel synthetic routes to spiroketals employed in his syntheses of (±) talaromycin B and (+) milbemycin β3".

Professor Kocienski also won a Pfizer Award in 1983

2. Dr E. J. Thomas, Dyson Perrins Laboratory, University of Oxford

"For his studies on the intramolecular Diels-Alder approach to the "carbocyclic" cytochalasans, for example in his synthesis of (–) proxiphomin".

Biology

4. Dr Christine Beedham, School of Studies in Pharmaceutical Chemistry, University of Bradford.

"For her contribution to the understanding of the metabolism of aza–heterocyclic compounds by the molybdenum hydroxylase enzymes"

5. Dr. Clive Robinson, Department of Clinical Pharmacology, Southampton General Hospital, University of Southampton

"For his work on synthesis and metabolism of eicosanoids in lung and the putative role of inflammatory mediators in bronchial asthma".

Pharmaceutical Sciences

3 Dr. John N. Staniforth, School of Pharmacy and Pharmacology, University of Bath.

"For his work on the physical properties of particulate solids used in pharmaceutical formulation design".

Animal Health Research

6. Dr Q. A. McKellar, Department of Veterinary Pharmacology, Faculty of Veterinary Medicine, University of Glasgow

"For his work on ostertagiasis with particular reference to the interaction between Ostertagia ostertagi parasites and the gastric mucosa of cattle".

Pfizer is a worldwide, research-based company with inter-related businesses in health care, agricultural, specialty chemicals, materials science and consumer products. The Company has a major commitment at Sandwich where it employs approximately 1600 people, about 600 of whom are engaged in new product research.

AIDS in an African context

Clues to the origin of the virus that causes AIDS continue to emerge from studies of African viruses. But African countries have more pressing concerns

SIR Fred Hoyle may hold the view that the AIDS (acquired immune deficiency syndrome) virus is of extraterrestrial origin, others may like to believe that it escaped from a germ-warfare laboratory (surely a better plot would involve an unscrupulous biotechnology company that made and released the virus but whose vaccine development department has been a failure), but in all likelihood the human AIDS virus is a descendant of a monkey virus. The link between the two may be the second type of AIDS virus, identified earlier this year in western Africa. That is one, but by no means the only, reason why there is an increasing interest in the study of AIDS in Africa.

The reason to believe that the second type of virus is a link between monkey viruses and HIV-1 (human immune deficiency virus type 1, otherwise acronymically termed HTLV-3, LAV or ARV) is that it is more closely related to the former than the latter, at least by relatively crude comparisons. But the situation is complicated by the isolation of two apparently different versions of the west African AIDS virus and of several apparently different monkey viruses.

On the evidence so far published, the two versions of the human virus are very similar in composition but only one causes AIDS. That one was isolated by Luc Montagnier's group from AIDS patients in Guinea Bissau and the Cape Verde Islands, and was named LAV-2 by them (Clavel, F. *et al. Science* **233**, 343–346, 1986). The group has since also isolated it from AIDS patients in neighbouring countries, renamed it HIV-2 and, as reported further on in this issue (Clavel, F. *et al. Nature* **324**, 691–695, 1986), molecularly cloned the virus. The other version of the virus has been found in nearby Senegal by Myron Essex's group and always in people without AIDS (Kanki, P. J. *et al. Science* **232**, 238–243, 1986). This virus is called HTLV-4.

Unfortunately, and largely because of the sorry state of affairs that exists between leading French and US AIDS researchers, there has been no direct comparison of HIV-2 and HTLV-4. Therefore it remains uncertain whether their obvious similarities betoken an identity — or rather a pseudoidentity, because, as Clavel *et al.* now report, different isolates of HIV-2 vary in much the same way as those of HIV-1. The more interesting possibility is that HTLV-4 differs from HIV-2 in some crucial way that accounts for its apparent lack of pathogenicity.

Whatever the relationship of HTLV-4 and HIV-2, both seem more closely related to monkey viruses than they are to HIV-1. With their molecularly cloned HIV-2, Clavel *et al.* now confirm that relationship in terms of the degree of hybridization between the nucleic acids of HIV-2 and the virus that is the cause of the AIDS-like disease of captive rhesus macaque monkeys. This virus, usually known as STLV-3$_{\text{mac}}$ but now called SIV (unwisely without a species designation) by Clavel *et al.*, is related both to a virus in healthy captive sooty mangabey monkeys and to a virus in healthy wild African green monkeys. It is with the latter, called STLV-3$_{\text{agm}}$ and now molecularly cloned (Hirsch, V. *et al. Proc. natn. acad. Sci. U.S.A.* **83**, 9754–9758, 1986), that HTLV-4 has been compared and shown to be closely related. Hence the hypothesis that an apparently harmless monkey virus, STLV-3$_{\text{agm}}$, was the origin of an equally harmless human virus, HTLV-4, which evolved into the pathogenic HIV-2, the ancestor of HIV-1. Although this hypothesis is not without its problems, it also leads to some predictions that will be put to the test once all the viruses are cloned and sequenced. So far only HIV-1 is sequenced but the HIV-2 sequence is well on the way and the others should follow soon, if all goes well.

It is conceivable, at least, that this line of research will provide compelling evidence of an African origin of AIDS. Although that would not exactly be welcome news in Africa, at least the time is past when such a notion could lead to vehement denials, largely for fear of stigmatization and, it seems, loss of tourists. With a few exceptions, African countries are now frank about their AIDS problem, as well they might be given its scale.

Worst affected are central African countries, of which Kenya, Zaire and Uganda are the best studied. Reliable figures, which have been hard to come by, are summarized in two recent reviews (Quinn, T. C. *et al. Science* **234**, 955–963, 1986 and *AIDS and the Third World*, The Panos Institute*, 1986). As in developed nations, most of the data come from the major cities where the problem is at its greatest. The highest rates of infection are invariably in prostitutes, with figures ranging from 27 to 88 per cent. More alarming are the figures of 10–20 per cent from blood donors and antenatal clinics, as these are not high-risk groups in Western terms.

All the African figures have to be taken in context. Is, for example, the high rate of infection in blood donors typical of the population from which they are drawn or is it exaggerated by infection in the course of previous blood donations? Are the high rates of infection in general the result of other sexually transmitted diseases which, because of the genital ulcerations they cause, facilitate infection by the AIDS virus? And what rate of increase underlies these figures? Unfortunately there are few longitudinal studies of infection in Africa yet, although Quinn *et al.* boldly state that the present annual incidence of infection is approximately 0.75 per cent among the general population of central and east Africa. Nor are there many random population surveys, but a 6 per cent rate of infection recorded in a neighbourhood survey in Kinshasa, Zaire, is an indication of how serious the problem is.

More serious still is the fact that even the most simple means of limiting the spread of infection are not routinely used in most central African countries. It is estimated that between 1,000 and 1,500 new infections a year would be prevented in one major hospital alone in Zaire if there was routine screening of blood donors for HIV-1. Only a few million dollars would pay for routine blood screening throughout central Africa. But the cost per test would be somewhere between 3 and 30 times the average sum spent on an individual's health care in Africa. The prospects of routine testing seem poor without the help of foreign aid. To put the overall financial problem even more starkly, according to Quinn *et al.*, "the cost of caring for ten AIDS patients in the United States (approximately $450,000) is greater than the entire budget of a large hospital in Zaire, where up to 25 per cent of the pediatric and adult hospital admissions have HIV infection."

It is in this context that it is hardest to have much sympathy with some of the endless wranglings that go on concerning nomenclature of the viruses, with the neocolonial way in which some of the foreign interest in African AIDS is manifested, and with the lack of cooperation between rival groups when cooperation would further hasten understanding.

Fuel technology

Control of nitrogen oxides

A. Williams

AIR pollution arising from the emission of nitrogen oxides, NO_x, from combustion taking place in boilers, furnaces and engines, has increasingly been recognized as a problem (see, for example, *Fourth Report from the Environment Committee, Acid Rain*, HMSO, 1985). NO_x has been implicated as a photochemical oxidant and a constituent of acid rain, as well as being a pollutant in its own right. As a consequence, stringent legislation to limit its emission has been introduced or is proposed in the next few years in many parts of the world, but particularly in the United States, Japan and western Europe.

Several methods for controlling NO_x emissions have been developed (for example, *Control Technology for Nitrogen Oxide Emissions from Stationary Sources*, OECD, 1983). Most of these have some unsatisfactory aspects, however, and there is a constant search for new control technologies. Elsewhere in this issue R. A. Perry and D. L. Siebers (*Nature* **324**, 657, 1986) propose such a new technique. This method, developed at the Sandia National Laboratories, Livermore, California, is based on adding isocyanuric acid to hot exhaust gases, the acid being produced from the thermal decomposition of non-toxic cyanuric acid above 330 °C

$$(HOCN)_3 \rightarrow 3\,HNCO$$

Because this new control method has some attractive features it is worthwhile looking at it in the context of the control strategies that are currently available. The engineering aspects of the control strategies available for both NO_x and SO_2 are under investigation by the Fellowship of Engineering in the United Kingdom and its results will be published next year.

The major sources of NO_x are stationary combustion sources, such as boilers and furnaces, and motor vehicles, although some NO_x is emitted from chemical processing plants. The primary pollutant produced is NO, although some NO_2 and N_2O can be formed, and the NO reacts in the air to form a mixture of NO and NO_2 (NO_x). First, thermal NO is formed in combustion chambers from the oxidation of N_2 by the oxygen present in the 'excess air' needed to carry combustion to completion. Second, NO is formed from fuel-nitrogen compounds present in coal or to a smaller extent in oil, but not in natural gas. Third, NO can be formed in fuel-rich flames where hydrocarbon radicals react with nitrogen, this source, which is normally small, is termed 'prompt-NO'.

Various NO_x control technologies have been directed at combustion chamber modifications or a flue-gas treatment called denitrification. The combustion chamber modifications involve techniques to reduce the flame temperature and/or to reduce the amount of oxygen available for primary combustion. In engines this can be achieved by lean-burn techniques or stratified combustion chambers. In boilers and furnaces it can be achieved by low NO_x burners that depend on carefully controlled mixing of fuel and air, by flue-gas recirculation, or by low-temperature combustion techniques such as fluidized bed combustion or catalytic combustion.

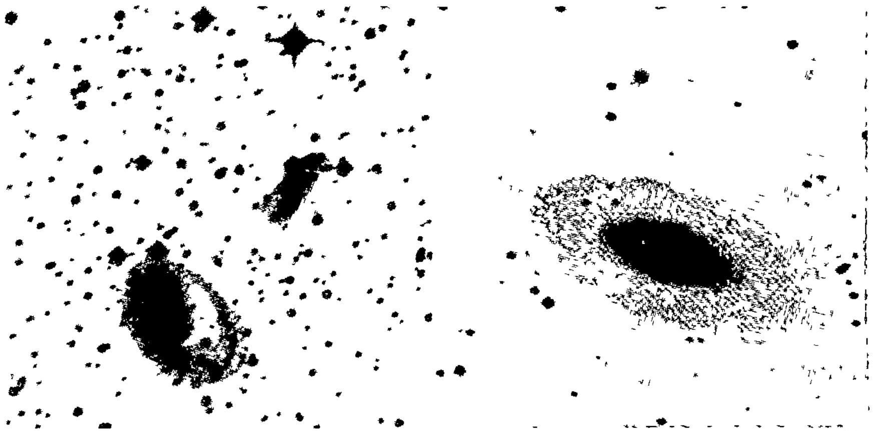
The NO_x regulations currently proposed are so strict that in the case of both engines and stationary combustion units it is becoming increasingly difficult to obtain the low concentrations of NO_x required by combustion modifications alone. Consequently, interest has centred on flue-gas denitrification for supplementing or replacing combustion control methods.

The methods available depend on the application and particularly whether the gases are clean or dust-laden. The most attractive methods involve (1) heterogeneous catalytic destruction usually based on precious metal catalysts and involving the reaction $2\,NO \rightarrow N_2+O_2$, (2) ammonia injection, called thermal de-NO_x, based mainly on the reaction $NH_2 + NO \rightarrow N_2 + H_2O$ and so on, (3) a catalytic version of the ammonia process usually called selective catalytic reduction, and (4) injecting methane or similar hydrocarbons to 'reburn' NO by reactions such as $CH + NO \rightarrow HCN \rightarrow CO + N_2$. The first of these methods needs a cleanish gas, such as engine exhaust or the flue gases from natural gas combustion, but needs controlled oxygen (air) addition. The other two need controlled ammonia or methane injection and controlled flue-gas temperatures and are really suitable only for large stationary plants. The applicability of many of these methods is limited where extensive heat recovery is required and the platinum-based catalysts, which operate down to 350 °C, look particularly attractive, if deactivation does not occur.

The new technique of Perry and Siebers therefore looks an attractive proposition. It provides a means of reducing NO_x levels down to those required by the most stringent regulations by passing the gas over the reactant without having to control the oxygen levels. It will operate over a temperature range of 450 to 900 °C, although at lower temperatures (100–450 °C) it actually produces NO_x itself. It seems clear that the work describes a technique that is a valuable additional NO_x control technology.

Their paper stems from earlier work (Perry, R. A. *J. chem. Phys.* **82**, 5485, 1985) that contains an interesting proposal about the chemistry leading to the formation of N_2O in some flames containing fuel-nitrogen. Although it has been known for several years that N_2O is formed during the combustion of organo-nitrites or nitrates (see, for example Gray, P. & Williams, A. *Nature* **188**, 56, 1960) it is a surprise that it can be formed in significant amounts as a result of the combustion of coal. The new work is therefore particularly interesting in that it proposes a control technology linked with these chemical routes and offers additional control mechanisms for future development. □

A. Williams is Professor of Fuel and Energy at the University of Leeds, Leeds LS2 9JT, UK.



JANE Few and Barry Madore, in a survey published in a recent issue of the *Monthly Notices of the Royal Astronomical Society* (222, 673–682; 1986), identify two sub-types of ring galaxies. On the left is a P-type ring galaxy showing the crisp, knotty structure of the ring itself, the displaced nucleus and companion galaxies. On the right is an O-type galaxy, showing the smooth structure of the ring and the centrally located nucleus. These data support the idea that P-type galaxies were formed from disk galaxies by the direct head-on collision with a companion and that O-type galaxies formed in isolation. □

Cellular signalling

A second messenger function for inositol tetrakisphosphate

Bob Michell

AN entirely novel concept entered our knowledge of how receptors send signals through membranes to the cell interior when it was realized that the receptor-activated hydrolysis of phosphatidylinositol 4,5-bisphosphate yields two second messengers rather than one Inositol 1,4,5-trisphosphate (Ins(1,4,5)P$_3$) and 1,2-diacylglycerol have different molecular targets within the cell, but they often act synergistically during the evocation of cell responses (reviewed in refs 1–3) Enzymic removal of the 5-phosphate of Ins(1,4,5)P$_3$, discovered in 1982, provided a perfectly respectable mechanism for its inactivation In the past year or so, however, it has become increasingly clear that there is a quantitatively important alternative pathway for the rapid metabolism of Ins(1,4,5)P$_3$ in stimulated cells, as a result of which it is phosphorylated to inositol 1,3,4,5-tetrakisphosphate (Ins(1,3,4,5)P$_4$), which is then dephosphorylated to inositol 1,3,4-trisphosphate, Ins(1,3,4)P$_3$ (see my recent News and Views article[4] and refs 5,6) It has been widely expected that Ins(1,3,4,5)P$_4$ or Ins(1,3,4)P$_3$, or maybe both, would function as additional intracellular messenger(s) generated by this increasingly complex signalling system, Irvine and Moor[5] now present the first evidence in support of this hope Using sea urchin eggs, they obtain evidence that strongly suggests that Ins(1,3,4,5)P$_4$ regulates the entry of calcium ions into these cells from the external medium

Whittaker and Irvine[7] were the first to show that injection of Ins(1,4,5)P$_3$ into sea urchin eggs suspended in a Ca^{2+}-containing medium causes the raising of a fertilization membrane, a response which seems identical to that produced by normal fertilization by sperm It is generally agreed that this response is mediated by a rise in intracellular Ca^{2+} that is fed both from internal Ca^{2+} stores and from the external medium Ins(1,3,4,5)P$_4$ does not mobilize Ca^{2+} from intracellular stores[6], so it was no surprise when it failed to activate eggs[5] But it has been clearly demonstrated that Ins(2,4,5)P$_3$ mobilizes Ca^{2+} from the same intracellular store as Ins(1,4,5)P$_3$, so its failure to raise a fertilization membrane was unexpected[5] Irvine and Moor surmise that the key to the difference between Ins(1,4,5)P$_3$ and Ins(2,4,5)P$_3$ might lie in the ability of the former to be converted to Ins(1,3,4,5)P$_4$ in the eggs into which it is injected, and wondered whether activation requires the simultaneous presence within the eggs of Ins(1,4,5)P$_3$ and of Ins(1,3,4,5)P$_4$ derived from it (Ins(2,4,5)P$_3$ is not an effective alternative substrate for Ins(1,4,5)P$_3$ 3-kinase, so it could not provide Ins(2,3,4,5)P$_4$ as an Ins(1,3,4,5)P$_4$ analogue) To test this idea, eggs were incubated in a Ca^{2+}-containing medium and injected with a mixture of Ins(1,3,4,5)P$_4$ and Ins(2,4,5)P$_3$ The results are startling This mixture of two ineffective inositol phosphates activates the eggs as effectively as Ins(1,4,5)P$_3$ alone As with other modes of egg activation, success with the Ins(1,3,4,5)P$_4$/Ins(2,4,5)P$_3$ mixture requires the presence of extracellular Ca^{2+} Irvine and Moor conclude[5] that Ins-(1,3,4,5)P$_4$ is likely to be the intracellular messenger responsible for initiating Ca^{2+} entry from the exterior, and that this is somehow dependent on the prior or simultaneous Ins(1,4,5)P$_3$-triggered discharge of the intracellular Ca^{2+} store They envisage that these two processes are coupled in some mandatory way such as that envisaged by Putney[8] his idea is that Ca^{2+} entering from the exterior does not move directly into the cytosol, but is routed through the Ins (1,4,5)P$_3$-sensitive pool, with influx particularly rapid when this pool is either partially or fully discharged

If future data confirm this view of events in sea urchin eggs and extend it to other cells, we now have all the key elements necessary to understand receptor-regulated Ca^{2+} mobilization into the cytosol of most stimulated cells Of course, Ins(1,4,5)P$_3$ and Ins(1,3,4,5)P$_4$ need to be both produced and inactivated in a coordinated way A remarkably tidy facet of this entire system is that the inositol polyphosphate 5-phosphatase that was originally detected as an Ins(1,4,5)P$_3$ 5-phosphatase may simultaneously inactivate both of these signals □

Atomic motion

Quantum fluctuations in sub-micron wires

Patrick A Lee

PHYSICISTS have long held the notion that measurements on a macroscopic sample are the same as the average over an ensemble of similarly prepared samples In the past two or three years, this notion has been challenged by a combination of two factors the ability to prepare small samples using micro-fabrication techniques, and the general availability of low temperature in the tens of millikelvin range The typical sample dimension is 0 05 µm diameter and 1 µm long, so that these 'small' samples still contain 10^8–10^9 atoms The surprise is that these samples, which are macroscopic on the atomic scale, already exhibit large fluctuations in their electric conductivity which also vary from sample to sample Furthermore, theoretical developments have led to a quantitative description of this phenomenon, and point to the possibility of detecting the change in the conductivity of a small metallic sample if the sample is perturbed in the slightest manner, even in the limit of displacing a single atom

These developments were initiated by the discovery that the resistances of small metallic wires (0 04 × 0 04 × 0 7 µm^3) exhibit random structure when a magnetic field is applied perpendicular to the wires[1] The structure is observable below 1 K, it increases in magnitude down to 10 mK where it is about a 0 1 per cent effect, it is reproducible upon cycling of temperature and magnetic fields, and it is a signature of a particular sample

At these low temperatures, the resistance is entirely due to the presence of impurities and imperfection in the sample and the motion of the electron through the sample must be described in terms of quantum mechanics A particularly illuminating way of describing the low temperature conductance G (inverse of resistance) of a disordered sample was provided by Landauer[2], who showed that G is proportional to the transmission probability of the electron wave through the disordered medium The proportionality constant is e^2/h which is a combination of fundamental constants with the dimension of conductance and equals 4 × 10^{-5} Ω^{-1} (The same combination is the unit of the Hall conductance in the quantized Hall effect)

The first step towards understanding the experiment was taken by Stone[3], who performed numerical calculations based on the Landauer formula for two-dimensional samples consisting of 40 × 400 sites and found fluctuations qualitatively similar to the experimental observation The idea is that according to Feynman's formulation of quantum mechanics, the transmission probability is given by a sum of the quantum amplitudes for many classical paths, and that the phase of each path is changed by the magnetic field in a random way As a result the transmission probability and therefore G exhibit fluctuations as a function of magnetic field However, numerical models showed a 10 per cent fluctuation and it was not clear how one could extrapolate results based on 10^4 sites to the experimental system with 10^8 atoms One might have guessed that as the sample size increases, the fluctuation will average away, but the numerical work showed that the magnitude of the fluctuation is almost independent of sample size

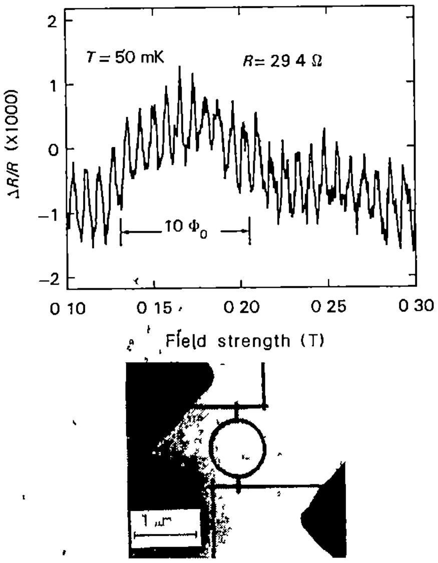

Fig 1 Variation of the resistance (R) of a metallic ring (photographed in the inset) with magnetic field The field strength is measured in tesla and is also shown in terms of the flux through the ring in units of the flux quantum $\Phi_0=h/e$ The oscillation with period h/e is the Aharonov–Bohm effect and the random structure it rides on is the universal conductance fluctuation The magnitude of both are of the order of $e^2/h \sim 4 \times 10^{-5}\ \Omega^{-1}$ in conductance units The inside diameter of the ring is 0 784 μm and the width of the wires is 0 041 μm (From ref 9)

The answer to these questions was provided by Lee and Stone[4] and independently by Altshuler[5] who showed analytically that if the question is posed in terms of ΔG, the root-mean-squre fluctuation in the conductance, instead of the percentage fluctuation,then at sufficiently low temperature ΔG is always of the order of e^2/h, independent of sample size and the amount of disorder, as long as disorder is weak and the sample is metallic The requirement of low temperature is that the electron should not suffer any inelastic collision as it traverses the sample For a 1-μm structure, this requirement is usually satisfied below 10 or 100 mK The prediction of this phenomenon of universal conductance fluctuation is consistent with both the numerical and experimental work and has now been verified in various experimental systems[6,7]

Universal conductance fluctuation is a consequence of quantum-mechanical coherence on a macroscopic length scale A most dramatic manifestation of this coherence is the Aharonov–Bohm[8] effect in normal metals, which was observed at about the same time as universal conductance fluctuation[9] (The Aharonov–Bohm effect is the idea that the electromagnetic potential alone, in the absence of any electromagnetic field, causes an observable quantum effect — a shift in the phase of the wavefunction) As shown in Fig 1, a small metallic ring is fabricated and its conductance is measured as a function of magnetic field perpendicular to the ring By extensions of Aharonov and Bohm's original arguments[8] which applied to electron motion in free space, it was predicted theoretically[10] that electron waves which propagate down the two arms of the ring would be phase-shifted by the magnetic field, and their interference would lead to periodic oscillation of the conductance The observation of these periodic oscillations (Fig 1) is a dramatic demonstration of quantum-mechanical coherence

One might worry that the amplitude of the periodic oscillations may be greatly reduced due to cancellations between the many Feynman paths with random phase which propagate down the arms But this is the same issue addressed by the theory of universal conductance fluctuation Thus, the magnitude of the periodic oscillation should be the same as the random structure, that is, of the order of e^2/h This is indeed the case for the data in Fig 1

The remarkable sensitivity of the conductance of a single sample to the magnetic field raises the following question how sensitive is the conductance to a change in the atomic configuration of a sample? The question was answered by Altshuler and Spivak[11] and independently by Feng, myself and Stone[12] who showed that changing the location of a single atom in a sample can, under suitable circumstances, lead to a conductance change of e^2/h as well and that this change is independent of sample area for thin films

This remarkable result is a natural consequence of the view of the electron motion as a superposition of many classical Feynman paths The point is that the classical motion of an electron across a strongly disordered metal is a random walk, which explores a large portion of the sample In fact, in two dimensions (thin films) the random walker visits a sizeable fraction of all the impurities, so that disturbing a single impurity affects the phase of a sizeable fraction of all the Feynman paths In other words, changing a single impurity has the same effect as replacing the entire sample According to the theory of universal conductance fluctuation, this leads to a change of the conductance of the order of e^2/h for highly disordered metallic thin films and wires Less dramatic, but still significant changes are predicted for bulk samples as well

Ideally, one would like to design an experiment to test this prediction, but nature appears to be kind enough to have provided an example Experimentalists at Purdue University[13], studying the resistivity of small wires and thin films, were perplexed by their observation that at temperatures below 1 K their data were not reproducible from run to run A more careful examination of the resistance as a function of time shows that it is time dependent, Figure 2 shows an example where the resistance makes two excursions in the period of an hour In this example, the resistance returns to the base line after a few minutes, but more complicated time dependence is also observed The experimentalists interpreted these jumps as being caused by the motion of a single atom or a small group of atoms and the magnitude of the jump is consistent with the theoretical prediction If this interpretation is correct, the motion of a single atom in a macroscopic metallic sample is indeed detectable It is not known what caused the atomic migration in the bismuth films at these low temperatures, but the effect may allow study of the dynamics of such slow configuration changes

Although the initial discovery of sample-specific fluctuations was made at low temperatures, it has become clear that quantum-mechanical coherence plays an important role as long as the inelastic scattering length greatly exceeds the mean free path, a condition which is satisfied

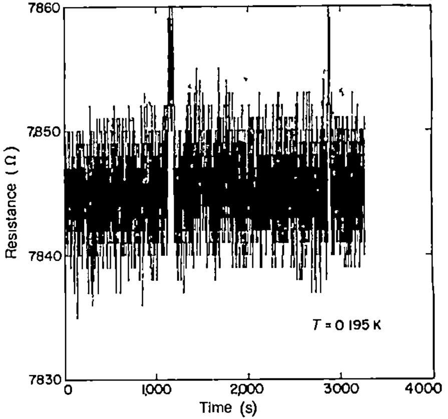

Fig 2 The resistance of a bismuth film (16 × 8 × 0 007 μm^3) at 0 195 K as a function of time in seconds The two excursions from the constant background at 1,100 and 2,900 s (rapid fluctuations are instrumental noise) are interpreted as being due to the motion of a single defect in the bismuth film (From ref 13)

even at room temperature if the metal is sufficiently disordered For example, Feng *et al* [12] point out that the sensitivity to impurity configuration provides an estimate of the magnitude of 1/*f* noise due to defect motion in highly disordered metals At the same time, it is likely that insights gained from the studies of electron wavefunctions will deepen our understanding of the propagation of classical waves such as electromagnetic or sound waves through a random medium □

Carcinogenesis

A superfamily of potentially oncogenic hormone receptors

Stephen Green and Pierre Chambon

UNDERSTANDING how patterns of gene transcription are controlled during the development of eukaryotic organisms and in terminally differentiated cells is an important goal of molecular biology This control appears to be achieved through the interaction of *trans*-acting proteins with *cis*-acting DNA promoter elements, which may result in a positive or a negative effect (see ref 1) Very few regulatory proteins have been characterized in higher eukaryotes Steroid hormone receptors are such a family of regulatory proteins, whose ability to control gene expression is dependent on the binding of their specific ligand Activation of transcription seems to result from the specific binding of the hormone–receptor complex to promoter 'enhancer' elements of target genes[2] Thus, the study of these receptors is of interest not only for elucidating how the receptor interacts specifically with its ligand, but also for understanding how this binding leads to the activation of transcription through specific protein–DNA interactions New work from four laboratories reported in this issue[3-6] brings us closer to understanding these mechanisms but also produces some apparent contradictions

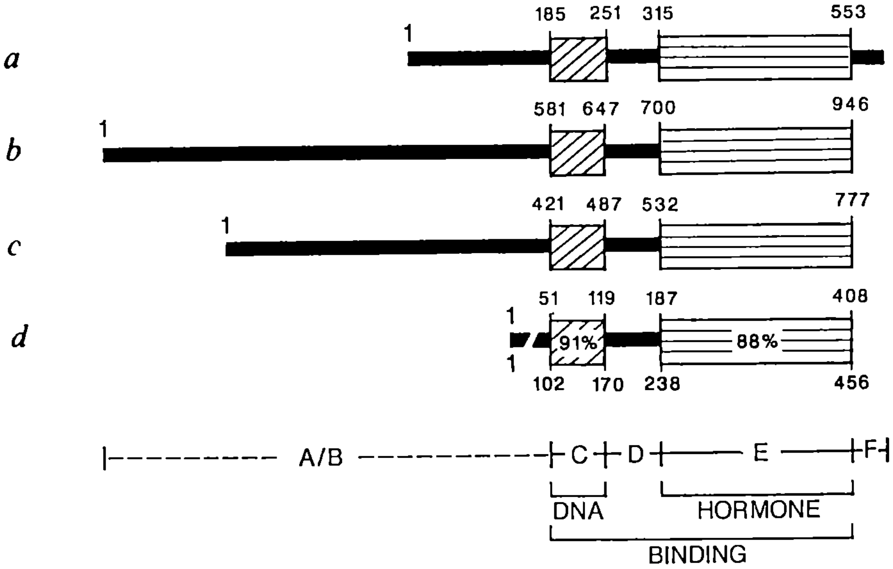
The recent cloning of glucocorticoid[7,8], oestrogen[9,10] and progesterone[11,12] receptors provides the first opportunity to investigate, at the molecular level, how transcription by RNA polymerase class B (II) is regulated in higher eukaryotes Sequence comparisons[10], together with mutation analysis[13,14], have defined two conserved regions that correspond to important functional domains (see figure) The putative DNA-binding domain is a highly conserved 66-amino-acid region (C) which has the potential to form two DNA-binding 'fingers' analogous to those proposed for the transcription factor TFIIIA (see refs 15 and 16), but involving two pairs of cysteines instead of pairs of cysteines and histidines[11] Results obtained with a chimaeric receptor show that region C determines the specificity of the receptor for the transcription of target genes[17] The hormone-binding domain (region E) is located in the C-terminal half of each of the receptors[13,14] The hydrophilic region D, which is variable in both length and sequence, may correspond to a hinge between the DNA- and hormone-binding domains Whether region A/B is required for activating transcription is not clear because analysis using insertional mutants of the human glucocorticoid receptor[14] indicates its importance for activation of transcription, whereas results obtained with deletion mutants of the rat glucocorticoid[18] and human oestrogen (Kumar, V *et al*, in preparation) receptors suggest that it is dispensable

Sequence comparisons revealed similarities between the product of the v-*erb*-A gene of the avian erythroblastosis virus and the human glucocorticoid[19] and oestrogen[9] receptors (see figure) This similarity is most striking in region C which is equally conserved when comparing these receptors and v-*erb*-A (about 50–60 per cent in each case) Because significant homology is also found in region E (although to a lesser extent, see figure), it was suggested that c-*erb*-A, the cellular counterpart of v-*erb*-A, is a receptor for a steroid-related ligand[10] Two reports on pages 635 and 641 of this issue[3,4] demonstrate, surprisingly, that the product of both a chicken[3] and a human[4] c-*erb*-A gene bind specifically thyroid hormones with high affinity (although the affinity with which the two receptors bind T_3 differs by an order of magnitude), and may therefore be the chicken and the human receptors for those hormones This possibility is further supported by the nuclear localization of the chicken c-*erb*-A product

The thyroid hormone receptor is known to be localized in the nucleus and it is believed that it modulates gene expression by a mechanism similar to that of steroid hormone receptors (see ref 20) Regions C and E of the thyroid hormone receptor may thus correspond to their DNA- and hormone-binding domains, respectively As region C of either the human and chicken oestrogen receptors[10] or the human and rat glucocorticoid receptors[21] are entirely conserved, it is surprising that C regions of the chicken c-*erb*-A and the human c-*erb*-A are only 91 per cent homologous, a value which is identical to the homology found between the progesterone and glucocorticoid receptors (see figure) These two c-*erb*-A products may thus correspond to different genes encoding receptors that bind the same hormones, but exhibit different target gene specificites This possibility is supported by the finding of several *erb*-A-related genes located on difficult chromosomes in the human genome[4] Studies on the transcriptional activation of thyroid hormone receptor-responsive genes using the two cloned c-*erb*-As are required to demonstrate definitively that they correspond to functional thyroid hormone receptors That steroid and thyroid hormones, which are neither structurally nor biosynthetically related, have receptors that have evolved from a common ancestor gene, suggests strongly that there is a large superfamily of genes whose products are transcriptional regulatory proteins All these proteins probably have similar DNA-binding domains, but it will not be surprising to find that the activity of some of them may have become independent of ligand binding, thus allowing them to act as constitutive transcription factors This superfamily could be comparable with that of the homoeobox-containing proteins that are also involved in the control of gene expression during development, but whose putative DNA-binding domain may contain the prokaryotic helix-turn-helix DNA-binding motif rather than DNA-binding fingers[16]

The classical model for steroid hormone action proposes that the hormone is required for translocation of the receptors to the nucleus and for its binding to the DNA-responsive elements of target genes (see ref 2) This model is based on the observation that the hormone is required for the receptor to bind tightly to the nucleus However, it has been shown more recently that the oestrogen (see ref 22) and the progesterone (see ref 23) receptors are localized, but weakly bound, in the nucleus even in the absence of hormone

What, then, is the role of the hormone? Could the hormone-free receptor, for instance, occupy the DNA steroid-



Schematic alignment of steroid and thyroid hormone receptor sequences The amino-acid sequences of the human oestrogen receptor (*a*), chicken progesterone receptor (*b*), human glucocorticoid receptor (*c*), and both the chicken (1–408) and human (1–456) c-*erb*-A proteins (*d*), were deduced from their complementary DNA sequences Alignment is based on amino-acid similarity and the numbers refer to the position of amino-acid residues The division of the steroid hormone receptors into 6 regions (A–F), based on a comparison between the chicken and human oestrogen receptors[10], is shown at the bottom of the figure The two highly conserved regions, representing the putative DNA-binding (region C) and hormone-binding (region E) domains, are shown as shaded blocks Little or no significant homology is observed when comparing other regions of the receptors (solid black lines) Comparison between the chicken and human c-*erb*-A protein sequences shows 91 and 88 per cent sequence identity in regions C and E, respectively Comparison between the various receptors in regions C and E show the following homologies (in per cent) C, steroid receptors/c-*erb*-A ~ 45–55, human oestrogen/chicken progesterone or human glucocorticoid receptors, 62, chicken progesterone/human glucocorticoid receptors, 91 Region E steroid receptors/c-*erb*-A ~20, human oestrogen/chicken progesterone or human glucocorticoid receptors, ~30, chicken progesterone/human glucocorticoid receptors, 55

responsive elements of target genes without activating their transcription? This important question is addressed in two papers on pages 686 and 688 of this issue[5,6] and in another which has just appeared in the *EMBO Journal*[23] Using the *in vivo* dimethylsulphate footprinting technique, the group of Schutz[5] shows that occupancy of the glucocorticoid-responsive element of the glucocorticoid-inducible liver tyrosine aminotransferase gene is influenced by the presence of the hormone and of its antagonist RU486 Protection of guanine residues within the glucocorticoid-responsive element is observed only in the presence of dexamethasone and not in the absence of hormone nor in the presence of RU486 Although a weak interaction of hormone-free glucocorticoid receptor with the responsive element cannot be excluded by these experiments, the results clearly support the notion that dexamethasone increases the affinity of the receptor for its target sequence

In contrast, the two other reports present *in vitro* data which suggest that glucocorticoid[6] and progesterone[23] receptors recognize preferentially their specific DNA-binding sites, irrespective of the presence of the hormone, and even when complexed with their common antagonist RU486 The group of Milgrom[24], which has studied the binding of highly purified hormone-free rabbit progesterone receptor to specific fragments of the target uteroglobin gene, concludes that the affinity of the receptor for its target sequence is not modified by the presence of the hormone or of its antagonist, and that specific recognition is achieved even at 0°C Willmann and Beato[6] have approached the same problem by studying the ability of crude rat liver cytosolic preparations of hormone-free glucocorticoid receptor to bind to the responsive element of the mouse mammary tumour virus long terminal repeat sequence Again, no effect of the hormone, or its antagonist, on the DNA-binding properties of the cytosolic receptor is found, although a heat-activation step (25 °C, 30 min) of the cytosol preparation is essential Thus, it appears that the hormone is not necessary for specific DNA-binding *in vitro*, whereas it is *in vivo*

There are at least two explanations that can reconcile these conflicting data As proposed by both Willmann and Beato[6] and Bailly *et al*[23], the receptors may be complexed *in vivo* with some protein(s) or structure(s), preventing their binding to the target-gene responsive elements Binding of the hormone to the receptor would induce the dissociation of such a complex, allowing the receptor to interact with its target sequences One possible candidate for such an inhibitor is the heat-shock protein of relative molecular mass 90,000 which, under certain conditions, readily associates with several steroid receptors[24] Alternatively, it cannot be excluded that extensive purification of the receptor or an *in vitro* heat-activation step may mimic the action of the hormone by artefactually inducing a conformational modification of the receptor required for recognition of specific target sequences This modification could correspond either to the 'unmasking' of a previously hidden, but potentially active, DNA-binding domain, or to a conformational activation of a previously inactive domain However, true affinity measurements (based on the 'on' and 'off' rates of the receptor to its target sequence) in the presence and absence of the hormone have not been performed in either of the two *in vitro* studies[6,23] This may explain some discrepancies between the results obtained *in vitro* by Willmann and Beato[6] and those previously reported by Bourgeois *et al*[25], who have also studied the effect of dexamethasone and RU486 on glucocorticoid-receptor binding to the mouse mammary tumour virus long terminal repeat Thus, until real affinity measurements have been performed, it still remains an open question as to whether the efficiency of receptor binding to responsive elements is independent of the presence of the hormone *in vitro* In fact the recent studies of Beato's group (personal communication) indicate that the *in vitro* 'on' and 'off' rates may be higher in the presence of the hormone This may result in a marked effect on the occupancy of responsive elements by the receptors *in vivo* where the number of non-specific, compared with specific, DNA-binding sites is very large

The avian v-*erb*-A oncogene, which cannot by itself induce cell transformation, enhances the erythroblast transforming potential of several primary oncogenes, such as v-*erb*-B (see refs 26 and 27) The v-*erb*-A gene product completely inhibits erythroblast differentiation into erythrocytes and allows transformed erythroblasts to grow in standard tissue-culture media, which has led to the notion[3] that in erythroid cells, v-*erb*-A interferes with ion transport systems and regulatory factors of differentiation Because of the sequence similarity between v-*erb*-A and steroid hormone receptors, it has been speculated[10,19,28] that v-*erb*-A exerts its effect either by mimicking or by competitively antagonizing the effect of c-*erb*-A on the transcription of target genes Assuming that the thyroid and steroid hormone receptors function similarly, it is intriguing that v-*erb*-A can exert its specific effects on erythroblasts even though it cannot bind thyroid hormones, presumably because of some of the many mutations present in its putative ligand-binding domain (region E)[3] It is likely that, because of other mutations[27], v-*erb*-A has acquired the ability to bind 'constitutively' to responsive elements of target genes Whether this would result in v-*erb*-A mimicking or competitively inhibiting (for example, because the truncation of region A/B in v-*erb*-A would prevent it from activating transcription) the effect of c-*erb*-A, and/or whether the two amino-acid substitutions that are present in the putative DNA-binding domain of v-*erb*-A[3] have resulted in changing its target gene speicificity when compared with c-*erb*-A, remains to be seen

If one assumes that the thyroid hormone receptor acts like steroid hormone receptors, the reports of Weinberger *et al*[4] and Sap *et al*[3] in this issue suggest that 'altered' enhancer factors may be important in oncogenic transformation by interfering with the transcriptional regulation of crucial target genes The well-known effect of the presence of oestrogen receptor on the growth of some human breast cancers (see ref 29) and the insertion of the hepatitis B viral genome into an *erb*-A-related gene of a human hepatoma[30] suggests that the superfamily of receptor genes contains several potential oncogenes encoding enhancer binding factors The polyoma virus enhancer can be activated *in trans* by expression of the c-Ha-*ras* oncogene and by the tumour promoter TPA[31] Furthermore, the activity of several viral and cellular enhancers can be repressed *in trans* by expression of the adenovirus immortalizing oncogene *E1A* (see ref 32) It may be possible, therefore, that alteration of enhancer elements of key cellular genes and/or of their binding factors correspond to crucial steps in many types of carcinogenesis □

Cosmology

Views with a gravitational lens

Rachel Webster and Michael Fitchett

GRAVITATIONAL lensing should in principle provide a fundamentally new technique for exploring the distribution of mass in the Universe, for determining cosmological parameters and for determining the properties of background sources For example, model fitting can determine the mass distributions of specific lenses and statistical studies can be used to determine the existence and density of populations of compact objects, strings or clumped dark matter In theory, constraints can be placed on the cosmological parameters H_0, Ω and Λ, but the realization of such measures may be difficult The amplification bias introduced by gravitational lensing will affect source counts of background objects and may either be skewing what we observe, or may serve as a natural telescope to probe the structure of objects at high redshift

The central point that emerged from a recent workshop*, however, was the need for verification that supposed gravitational lenses are indeed what they have been claimed to be Because one can in principle learn a great deal from either a particular instance of gravitational lensing, or a well-defined sample of multiply imaged quasars, it is important that a strict procedure is developed to confirm the status of a lens When the first candidate lens, 0957+561A,B, was discovered[1] in 1979, it was subjected to rigorous scrutiny Observations in a range of wavelengths and the identification of a reasonable candidate for the lens object have served to strengthen the case that the two images observed are of the same quasar Of course, if one hopes to learn something about the distribution of dark matter, the identification of a candidate lens object should not be a requirement, and the emphasis switched to other properties of the system A further eight candidates have now been added to the list It was not until the wide separation lens 1146 + 111B,C (at an image separation of 157 arc s it is about 20 times larger than any of the previous candidates) was mooted[2] that rigorous testing was again considered

Both necessary and sufficient conditions for lens identification were discussed by Jacqueline Hewitt (Haystack Observatory) and Irwin Shapiro (Harvard) Multiple images are seen along different photon paths This gives rise to spectral differences between the images, a time delay and perhaps a velocity difference If there is intrinsic variation in the source, not only will the spectra be different at one instant in time, but each will also vary with time Variation in the lens potential will change the relative amplifications of the images with time, and in particular amplifications of different regions of the image Once the tolerances in velocity, spectra and spectral changes for two images of the same quasar have been calculated, a sufficient set of conditions for the positive identification of a lens needs to be determined Possible tests include redshift, spectra, image morphology, identification of the lensing object and its effect on other background sources, time delay, polarization and parity The last two tests can easily be applied only to radio quasars Where such data are available, as in the case of 0957+561A,B, the case for lensing becomes very strong For optical quasars however, if no deflecting object is seen, definitive identification relies not only on determination of the redshift and spectra, but also on the measurement of a time delay As there are ten known optical quasars to every one known radio quasar, this ratio will be reflected in gravitational lenses, and an efficient technique for verifying optical candidates is required

Reports of systematic surveys for multiple images by four groups were highlights of the meeting Hewitt reported on a survey[3] with the Very Large Array This collaboration has identified a good candidate lens, 2016 + 112, and Hewitt described a further two candidates This survey is a sensitive probe of matter clumped on scales of $10^{10} - 10^{12}$ times the mass of the Sun, and already the authors can derive a conservative upper limit of $\Omega_{Lens} \leqslant 0\ 7$ for masses in this range Marc Gorenstein (Harvard) described a new survey using archive Very Long Baseline Interferometry data which will be sensitive to multiple images in the range 0 1 – 1 arc s This is the range of separations expected by galaxies acting as lenses John Stocke (Joint Inst of Lab Astrophysics) reported a study of X-ray active galactic nuclei selected near bright foreground galaxies These sources show some evidence, both in redshift distribution and in the ratios of X-ray to optical fluxes, of being micro-lensed by stars in the foreground galaxy One of us (R W) described an automated survey for optical candidates for gravitational lensing This study uses the automated plate measuring machine at Cambridge, United Kingdom automatically to select quasar candidates with possible image multiplicity Already this study can place limits on the numbers of lenses with separations in the range 10 arc s to 2 arc min (there are no candidates in a sample of about 2,500 quasars), and it can accumulate a substantial statistical sample of gravitational lenses in time

---

*The gravitational lensing workshop was held at the Department of Astronomy, University of Toronto and the Canadian Institute for Theoretical Astrophysics on 3 – 4 October 1986

Apart from the surveys, it became apparent that two other systematic monitoring projects are required First, the known candidates need to be regularly monitored to determine time delays C Vanderreist (Meudon Observatory) presented data for 0957+561 collected over a six-year time base So far a unique time delay cannot be determined from the data

Second, as Shapiro emphasized, none of the data collected so far gives a definitive measure of the time delay, to make use of information about the individual variations more needs to be known about the general population of quasars Not only do we need to know how quasars vary spectrally one from another, but also we need to know more about the power spectrum of the intrinsic variability

Peter Schneider (Joint Inst of Lab Astrophysics) distinguished between linear and non-linear cases of lensing In the former case, the optical depth in lenses is small, and reasonable progress can be made in analytically solving problems such as the effect of gravitational lensing on source counts In the non-linear case more than one strong lens event affects the photon path, and global problems need to be solved numerically A particular example of the latter is micro-lensing where the photon beam passes through a dense field of compact objects A second area of theoretical work is the modelling of specific instances of multiple images In most cases the modelling proceeds by trial and error until a single solution is found Such solutions are never unique, and in fact no systematic method for examining the ensemble of posible solutions has been developed Roger Blandford (California Institute of Technology) and colleagues are evaluating image parameters for different lens potentials to allow the most probable mass distribution in the lensing object to be determined

Third, the effects of a clumped matter distribution on the measurements of cosmological parameters was discussed by Charles Dyer (Toronto) In particular, many weak lenses can significantly affect background source amplifications[4] Myeong-Gu Park (Princeton) described a calculation which uses the known separations of double images to place limits on the cosmological parameters Λ and q_0, in particular $q_0 \geqslant -2\ 35$

Four new applications of lensing were discussed Bohdan Paczyński (Princeton) discussed the possibility that some of the gamma-ray bursts observed may be multiple images of the same event Such an observation would be evidence for clustered micro-lenses, the main difficulty in verifying this hypothesis is the determination of an accurate position for each individual burst Robert Wagoner (Stanford) explored the possibility of using supernovae as probes of dark compact objects He presented detailed calculations of the light curves expected for Types I and II supernovae which had been micro-lensed, and dicussed the possibility of actually observing such an event in a distant galaxy Ulf Borgeest (Hamburg) described a parallax method, requiring a baseline of about 0 1 AU, which would allow the determination of both the size of the quasar emitting region as well as the transverse velocity of the lens Borgeest also reported a method for using time delays to determine the mass of the primary galaxy in the lens

The wide separations of the observed doubles, and the absence in most cases of a suitable candidate for the lensing object, pose significant problems Blandford pointed out that if quasars are clustered like galaxies then one might predict a few correlated quasar pairs in the known sample of quasars[5] If, however, the multiple images without suitable lens objects are gravitationally lensed, then the mass distributions of the lenses have high mass-to-light ratios and cannot be composed of normal stellar material Thus the verification of candidate lenses becomes of central importance ☐

Developmental biology

New data from mammalian homoeobox-containing genes

Michael H L Snow

SERENDIPITY gave us the homoeobox[1], a highly conserved DNA sequence of about 180 base pairs, first found in several *Drosophila* genes that control segmentation Homoeoboxes were also detected in other segmented invertebrates and in several vertebrates including mammals, giving rise to the view[2] that this small DNA segment would serve to identify segmentation genes This notion has since been revised because echinoderms and molluscs, not generally regarded as segmented, also have homoeobox-containing genes[3] The recent demonstration[4] that the *Drosophila* homoeobox-containing gene *Zerknullt* (*zen*) is transcribed only in dorsal regions without segment specificity suggests that these genes have a wider scope than the organization of the anterior–posterior axis of the embryo The new data of Gaunt *et al* and Mavilo *et al* on pages 662 and 664 of this issue[5,6] add to our understanding of the specificity of expression of mouse[5] and human[6] homoeobox-containing genes

The possibility that homoeobox-containing genes specify positional information in the embryo is still high and it is this aspect of patterning in morphogenesis that underlies the considerable interest in

Mouse homoeobox-containing genes

Name of gene	Chromosome	Synonym	Ref	Best homologies (per cent nucleotides amino acids)

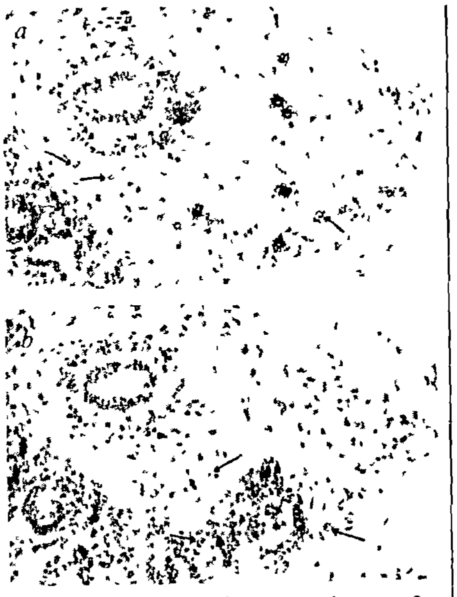
mammalian homoeoboxes. It has not been possible so far to analyse developmental mutants in mammals (principally in the mouse) with the thoroughness that has been applied to *Drosophila* but it is hoped that the homoeobox will enable us to identify and isolate such genes. So, how far have we got?

Six homoeobox-containing genes have been identified in the human and a dozen in the mouse (see table). As in *Drosophila*, these genes seem to be clustered and to show temporal and spatial restriction in transcription. *Hox-2.1* transcription, for example, is detectable in mouse embryos as early as 7.5 days post coitum (during late primitive streak stages of gastrulation), shows peak levels in 11.5–12.5-day-old embryos and is enriched in spinal cord. Recent work with *Hox-2.1* using Northern blot analysis and *in situ* hybridization detects transcripts in embryonic kidney and in the mesodermal component of the developing lung (P. Holland, B. Hogan and R. Krumlauf, in preparation) and show also that transcription is temporally related to the differentiation of F9 embryonal carcinoma (EC) cells (R. Krumlauf, personal communication). In this latter system the duration of the transcription phase and its position in the differentiation sequence is related to whether differentiation is towards visceral or towards parietal endoderm. The mouse *Mo-en.1* gene is also differentially expressed during differentiation of EC cells[7]. Gaunt *et al.*[5] in this issue describe similar differential expression of the mouse *Hox-1.4* (*Mo10*) gene by *in situ* hybridization. Here, transcription is again detectable at 7.5 days and is later found confined to spinal cord, mesonephric kidney and somites. The human homoeobox genes described by Mavilio *et al.*[6] in this issue likewise show considerable stage and organ specificity in expression. All mammalian homoeobox genes show similar restrictions in expression to some extent. What do the data tell us?

The short answer is very little beyond what I have discussed above. One problem is the difficulty in defining comparable aspects of mammalian and *Drosophila* development, and this is severely complicated by technical limitations in the analysis of the mammalian embryo. The extremely powerful genetic analyses in *Drosophila* support and are reinforced by the ability to detect the earliest transcriptional activity by Northern blot analysis, to locate it accurately by *in situ* hybridization, and to locate translation by detection of protein products. The data are consistent, showing the onset of gene activity — with known developmental consequences — at or shortly after cellularization of the blastoderm.



Kidney of 14.5-day-old mouse embryo. *a*, *In situ* hybridization with the anti-sense probe to mouse ε-globin. Heavy label localized over nucleated erythrocytes of yolk-sac origin. Arrows indicate three enucleated erythrocytes that originated from the liver. *b*, Control hybridization on adjacent section with the sense strand. Arrows indicate three nucleated yolk sac-derived erythrocytes which show up as positive in *a*. Probe donated by Andy McMahon, hybridization by Peter Koopman and Alex Reid.

The luxury of a four-pronged attack is not possible in the mammalian embryo. No genes are clearly definable as homoeotic or segmentation, although there are candidates for the latter[8], and no antisera against homoeobox gene products have yet been described. So we have only the relatively insensitive transcription analyses (Northern blots and RNase protection assays) and the potentially very useful *in situ* hybridization techniques. At the moment neither technique alone tells us very much. Transcription analysis requires that tissues can be dissected in sufficient quantity and is therefore applicable only to late embryonic or fetal stages if spatial distribution of transcripts is to be studied. This is long past the time that positional cues associated with lineage definition are likely to be needed. Furthermore, any small population of positive cells, for example, stem cells, may well be swamped by a mass of non-transcribing tissue. For earlier, more interesting stages, *in situ* hybridization is the technique of choice: the 7.5-day-old mouse embryo will yield less than 20 ng of messenger RNA and although it is possible to accumulate material for transcription analysis from parts of these embryos it is clearly a daunting task and not suited to the present impatient scramble to publish homoeobox data. The *in situ* hybridization technique is difficult to apply to mammalian embryonic tissue. Non-specific binding is a common, but recognizable, artefact[9] so it is imperative that rigorous control hybridizations, which should include a probe whose distribution is predictable in addition to the non-hybridizing, non-complementary 'sense' strand of the probe under study, are not only carried out but also displayed alongside the hybridization with the complementary anti-sense strand of interest.

It is possible, when cell discrimination is helped by histological parameters, to locate accurately *in situ* hybridization signals to individual cells (see figure), but where morphology does not assist it can be far from easy. Even if such data were to be acquired for 7.5-day-old mouse embryos it would then leave the not inconsiderable problem of relating any patterns found to known organ-specific transcription shown in fetal stages. The fate maps and lineage data that exist for these early stages only relate to development up to about the 10-somite stage[10], that is at least 24 hours before the primordia of many organs currently associated with homoeobox transcripts are found and 3–4 days earlier than the regional transcription analyses. Meanwhile, there are groups of apparently disparate organs expressing homoeobox genes at various developmental stages and we have little idea of what, if any, common feature they reflect. There are representatives of induced and inducing tissues, derivatives of different primary germ layers and organs which seem temporally and spatially unrelated in their origins. It may be a misleading coincidence, but the homoeobox-positive tissues equate roughly with those organs with determinate numbers of structural units, and negative tissues seem to be those that retain hyperplastic abilities throughout life[11].

Drosophila shows determinate development from the blastoderm stage. Although the information from *Drosophila* is not entirely straightforward[12], with curious gene interactions requiring explanation, the general picture is clear. The distribution of homoeobox gene transcripts is adequately linked through fate maps and genetics to later phenotype. There is some way to go before a similar state is reached with mammals and before we understand what their homoeobox-containing genes may do. ☐

Mitochondrial DNA

Rearranging the plant genome

Ronald A. Butow

THE tendency of many plant mitochondrial genomes to undergo extensive rearrangements provides a satisfying framework for understanding the phenomenon of cytoplasmic male sterility (CMS), a maternally inherited defect common to many higher plants that impairs the development of pollen. Some extraordinary examples of the molecular basis for CMS in plants such as maize, sorghum and petunia were provided at a recent conference*.

The mitochondrial genomes of higher plants tend to be very large (200–2,400 kilobases) compared with other organisms. The presence of many direct repeats within some plant mitochondrial DNAs can lead to a profusion of subgenomic units that arise by recombinations across the repeat elements, as was shown for maize (D. Lonsdale, Plant Breeding Institute, Cambridge), wheat (F. Quetier, Université de Paris-Sud, L. Bonen, University of Ottawa) and *Oenothera* (A. Brennicke, Universitat Tubingen). A somewhat simpler picture obtains for species of *Brassica* the mitochondrial genomes of related species are roughly the same size, but they vary in the number and distance between repeats on the 'master' mitochondrial genome. This variation neatly accounts for the number, size and, in some cases, compete absence of subgenomic elements (J. Palmer, University of Michigan).

As if the presence of repeats leading to recombinational partitioning of plant mitochondrial genomes is not complex enough, on closer scrutiny, other sub-stoichiometric sets of differently rearranged species are also apparent in maize mitochondria (P. Issac, University of Edinburgh). These sub-stoichiometric populations, called sublimons, are maintained through many generations, and thus must somehow compete with the 'major' mitochondrial DNAs in that plant. Conventional thinking about the drive to segregate pure populations of mitochondrial genomes must be refined to consider the origin of sublimons by continued recombination or replicative persistence, and perhaps occasional amplification, in which they may eventually take over the population.

So where does CMS fit into this picture of a promiscuously rearranging genome? In maize, CMS is associated with C, T and S cytotypes, whereas normal male-fertile strains are designated N. Compared with N strains, mitochondrial DNA from C male-sterile cytoplasms show three striking rearrangements that result in the formation of chimaeric genes (R. Dewey, North Carolina State University) first, the 5′ flanking region of the ATPase 9 gene has been replaced by sequences of unknown origin, second, the 5′ ATPase 9 sequences plus a small amount of the coding region are now found upstream of an open reading frame (ORF) originating from the chloroplast genome, which, in turn, is fused in-frame to the ATPase 6 gene, and third, the replaced ATPase 6 sequences are fused in-frame to the cytochrome oxidase 6 gene, whereas the displaced cytochrome oxidase 6 sequences end up in a region with no ORF.

The mitochondrial genome from T strains which are not only male sterile, but are also susceptible to toxin from the fungal pathogen *Helminthosporium maydis*, contains a rearrangement that is perhaps more bizarre than C. No less than seven recombination events must have taken place to create a chimaeric gene containing ATPase 6 sequences, a region 3′ to 26S ribosomal DNA, a portion of the interior of 26S ribosomal DNA and a transfer RNA (Arg) derived from the chloroplast genome. Earlier work (C. Leaver, University of Edinburgh) showed that a novel polypeptide of relative molecular mass 13,000 was synthesized in the mitochondria of T strains. It now seems clear that this polypeptide is the product of this chimaeric gene, also called ORF 13. A precise correlation can now be made between restoration of fertility and expression of ORF 13. In one case of a fertile, toxin-resistant mutant of T, two changes were detected in ORF 13 a single G-to-A transition in the reading frame, and an adjacent 5-base pair insertion creating a frameshift, which may have occurred by a gene conversion from flanking DNA sequences 3′ to the 26S ribosomal RNA gene (R. P. Wise, University of Florida). In other cases, mutation to fertility is caused by additional rearrangements that result in the deletion of the novel gene (W. Rottman, Plant Breeding Institute, Cambridge, C. Fauron, University of Utah). Restoration of fertility can also come from post-transcriptional processing activities that reduce the levels of translatable ORF 13 messenger RNA (Dewey, A. Abbott, Clemson University).

The picture is less clear for CMS-S. Male steriles of the S type have two linear DNA plasmids in their mitochondria, S1 and S2, that can integrate into the mitochondrial genome. In some nuclear backgrounds, reversion to fertility is always associated with the loss of S1 and S2 (E. Earle, Cornell University), although this is not always the case in other nuclear backgrounds (S. Gabay-Laughnan, University of Illinois). S-specific gene products have been identified (G. Zabala, University of Illinois, Leaver), but where S1 and S2 are present in fertile revertants, there are no apparent differences in the synthesis of the plasmid-encoded proteins examined so far.

That the nuclear context can be important in expression of the CMS trait is also evident from studies with sorghum. A variant cytochrome oxidase subunit I gene has been identified (J. Bailey-Serres, University of California, Berkeley) containing both 5′ and 3′ rearrangements. These result in the synthesis of a long form of the protein (relative molecular mass 70,300) — the largest cytochrome oxidase subunit I polypeptide identified to date. Although the precise relationship of this rearrangement to CMS is not completely known, some lines containing the variant gene are male sterile whereas others are fertile. In either case, there are no obvious effects on cytochrome oxidase activity.

Petunia provides another example of the association of CMS with mitochondrial gene rearrangements (S. Izhar, Volcani Center, Israel, M. Hansen, J. Rasmussen and H. Nivison, Cornell). Here, recombination leads to the formation of a chimaeric gene between ATPase 9, cytochrome oxidase subunit II (COII) and DNA sequences from an unidentified reading frame. This fusion gene is expressed in male-sterile lines, as are the intact copies of ATPase 9 and COII genes. Expression of the chimaera seems to be unaffected in the presence of a dominant nuclear restorer gene, but preliminary evidence suggests normal COII expression is increased in a restorer background (Nivison).

It is clear from most of the evidence presented that some restorer genes function either by lowering or eliminating the expression of novel proteins encoded by rearranged mitochondrial DNA in male-sterile lines or, in some way, by overriding their presence. It seems reasonable to imagine that these novel proteins, which are probably located in the inner mitochondrial membrane, cause some mitochondrial dysfunction that becomes limiting at a critical step in microsporogenesis. But what this dysfunction might be is a complete mystery. In a related maternally inherited phenomenon in maize called non-chromosomal stripe, novel mitochondrial DNA rearrangements were identified — although not in any known genes — that result in severe alterations in mitochondrial (and chloroplast) morphology (K. Newton, University of Missouri). Because these plants show abnormal growth, a more immediate effect of mitochondrial dysfunction seems likely. ☐

Microtubule dynamics

SIR—Although Williams, Caplow and McIntosh[1] correctly emphasize the important contribution of Horio and Hotani[2] in verifying, by real-time experiments; the concept of the dynamic instability of microtubules, some of their points are off the mark and they have missed an opportunity to evaluate the proposed explanations for dynamic instability in terms of these and other recent experiments

First, dynamic instability was never meant to imply that shrinking microtubules would always depolymerize to completion Although we pointed out that the rate constant for this transition would be hard to measure, our own data suggested that microtubules could in fact transit from shrinking to growing[3,4] What would determine whether a microtubule disappears, in addition to chance, would be its length, the experimental conditions and, probably most importantly, the purity of the tubulin In the theoretical work of Chen and Hill recapping rates are also explicitly included[5] The unusual characterisitic of microtubules is that the growing and shrinking transients make such large excursions It is less surprising that in some circumstances microtubule number actually decreases Therefore there are no real inconsistencies between the Horio and Hotani data and ours, except perhaps that under their conditions the excursions are somewhat smaller than those indirectly estimated from our steady-state experiments

A second issue is whether length redistributions at steady state[4] are due to growing and shrinking transitions in microtubules or due to annealing of polymers Although Williams *et al* point out that the Horio and Hotani results dispel any doubt that extensive growing and shrinking transitions are continually occurring, they suggest that annealing could have contributed to the magnitude of our original findings They fail to mention, however, that in a subsequent paper annealing was found to make only a very small contribution to steady-state length redistributions[6] Annealing is an interesting reaction but most likely to occur far from steady state and at very high concentrations of microtubule ends

It is worth reconsidering the original GTP cap model[7] as it was applied to dyna/ic instability[4] in light of the new Horio and Hotani data One reason we favoured the GTP cap model was that, in order not to violate thermodynamic principles, energy input from GTP hydrolysis is required to support continuous growing and shrinking[8] A second reason was to explain our observation that the probability of a microtubule starting to shrink was inversely related to its growth rate In the Chen and Hill simulation[5] virtually all transitions must occur on the minus end, as it is the slow growing end Yet Horio and Hotani find transitions on both ends and even a greater frequency on the faster growing end This is inconsistent with the original model[9] where GTP hydrolysis occurs at a fixed rate once a subunit is incorporated into the lattice In this simple model (Fig 1*a*) a subunit in the interior of the polymer cannot know which end it is near and hence the hydrolysis rate of all subunits in the interior of the polymer would be the same The faster-growing end would leave behind it a larger number of GTP-containing subunits and the GTP cap should be lost more frequently on the slower-growing end Thus the slower-growing end necessarily has a higher probability of transition to shrinking behaviour

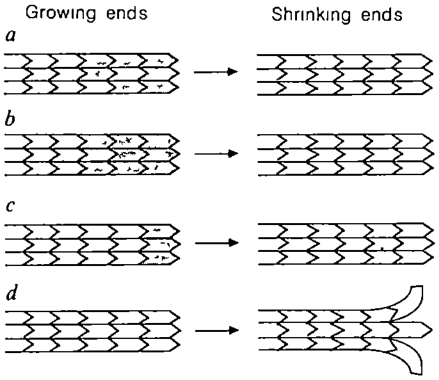

Fig. 1 Models for the molecular events that cause a growing microtubule end to start shrinking spontaneously The chevrons show the inherently asymmetric tubulin subunits in the lattice The blank chevrons are GDP-containing subunits and the stippled chevrons are GTP-containing subunits Note that the barbed end of the chevrons will be exposed at the other end of the microtubule (not shown)

Any explanation of Horio and Hotani's data must make use of structural differences at the two ends of the microtubule Presently we can see three ways of achieving this The first restricts GTP hydrolysis to the zone of subunits in contact with the GDP liganded core of the microtubule[1,10] In contrast to the previous model a subunit can tell which end it is near by which portion of the molecule is contacting subunits that have already hydrolysed their GTP In Fig 1*b*, for example, the pointed end of the GDP subunit is interacting with the barbed end of the GTP subunit, on the other end of the microtubule this relation is reversed This means that on one end of the microtubule (shown) GTP hydrolysis is induced by the pointed end of a GDP subunit, whereas on the other end (not shown), it is induced by the barbed end These different structural interactions could induce different rates of hydrolysis at the two ends, and thus the relation between growth rate and transition probability can be different at the two ends

The second possibility (Fig 1*c*) invokes a very minimal GTP cap, it is a model patterned after the conclusions of some recent work on actin by T Pollard[11] In his model, whether the polymer grows or shrinks depends only on the nucleoside composition of the terminal subunit or subunits Hydrolysis is effectively instantaneous for interior subunits, but slower for terminal subunits As the two ends of a polymer are structurally different, this could lead to different hydrolysis rates for terminal subunits at the two ends, and again to a different relationship between transition probabilities and growth rates at the two ends The complexity of microtubule structure means that there are many more possible terminal configurations than for actin filaments and this might extend the concentration range of free tubulin over which transitions would be observed Furthermore, rapid shrinking might generate conformations that make recapping difficult

The third possibility uncouples GTP hydrolysis from a structural transition at the end of the polymer lattice which initiates rapid disassembly (Fig 1*d*) The terminal subunits retain the GTP conformation for a period after hydrolysis (which is concomitant with assembly) and shrinking behaviour is initiated by a spontaneous fluctuation whose rate could be different at the two ends of the polymer The real situation could of course include elements from more than one model

One of the unique features of all these models for dynamic instability is that the stability of the polymer is regulated by reactions at the very ends of the microtubules But this potentially important biological property[8] is also an experimental difficulty as at any given time almost all subunits in the polymer and in solution are not carrying out important reactions The work of Horio and Hotani has dramatically demonstrated that the behaviour of individual polymers cannot be inferred from the behaviour of bulk populations It has further focused attention on the structure and enzymatic properties of the ends of polymers, a problem whose solution will require yet more ingenious experimentation

Preservation in bogs

SIR—Doran *et al* (*Nature* **323**, 803, 1986) have shown reasonable histological preservation of 8,000-year-old brain tissue from a bog site, yet they have not given an explanation for why the tissue preservation should be so good We suggest that it is due to tannic acid and related compounds contained in the bog fluids We have demonstrated excellent ultrastructural preservation of osteocytes from the 11,000-year-old antlers of an extinct Giant Irish Deer In this case preservation in the bog environment is so good that cytological features, such as mitochondria, rough endoplasmic reticulum, Golgi elements and nuclear pores are clearly demonstrated

How many reactor accidents?

SIR—Edwards[1] is correct that Islam and Lindgren[2] have failed to recognize that their distribution function is a likelihood function But he is incorrect in asserting that their conclusions are unwarranted and in assuming that physicists do not know how to work with small samples In fact Islam and Lindgren's likelihood function has been used in particle physics for over fifty years to make estimates of particle decay rates when the number of events in an experiment is small[3] Their approach yields not only estimates of the accident rate and probabilities but also the familiar standard errors and confidence limits without resort to Edwards' less familiar support function

The estimate of r, the accident rate, is given by the maximum of the likelihood function The standard error is conventionally quoted as the value(s) of r for which the likelihood L, falls to $e^{-1/2}$ of its maximum value And the (one-tailed) confidence limits on r are set by solving for r in the integral equation,

$$\int_r^{\infty} L_N \int \mathrm{d}r = P$$

where L_N is the normalized likelihood function These values of r can then be used to obtain estimates, standard errors and confidence limits on the probability P_T of accidents within the next T years

The two events over a cumulative 4,279 reactor years of operation[4] give the estimate $r=1/2{,}140^{+2\ 620}_{-1\ 000}$ reactor years with a one tailed 95% confidence limit $r>1/5{,}240$ reactor years In the next ten years 28 reactors are expected to be decommissioned and 156 are expected to come on line giving 4,900 reactor years of operation[4] The probability of one or more accidents in the next ten years is then $P_{10}=0\ 90^{+0\ 09}_{-0\ 26}$ with a 95% confidence level of $P_{10}>0\ 60$ Thus one has a quantitative estimate of how small the probability of accident is likely to be

Given that there have been two major accidents in the world's reactor inventory over 4,280 reactor years of operation the odds are 20 1 ($p>95\%$) that in 100 identical ensembles of reactors 60 ensembles will have one or more accidents within ten years A similar calculation shows that even if the world's reactors are phased out over the next 25 years the probability of major accident is $P_{25}=0\ 994^{+0\ 005}_{-0\ 09}$ with $P_{25}>0\ 88$ at 95% confidence

3 Brody, A R *et al* *Fedn Proc* **44**, 2596-2601 (1985)

SIR—Wolstenholme *et al*[1] have probably observed a well-preserved area of a meshwork of the nuclear lamina lining the nucleoplasmic surface of the inner nuclear membrane which supports the interphase chromatin It is unusual to observe any remnant of lamina in a metaphase preparation, but two chromosomes in the figure appear to be sticking to lamina

Full boxes in the pattern could represent the cytogenetic manifestation equivalent to the points of anchorage of the interphase chromosomes (telomeric ends and fragile sites) onto the laminar surface, thus reflecting the packing of chromosomes during interphase in a 'coded' form The average crossover space of the human lamina is 0 52 µm A 'decoded' picture of the pattern of native nuclear lamina of *Xenopus laevis* oocytes can be found in a past issue of this journal[2]

Archaeopteryx, the primordial bird?

SIR—In view of the highly critical review of our book *Archaeopteryx, The Primordial Bird A Case of Fossil Forgery* (*Nature* **324**, 185, 1986) I would like to bring to your notice recent developments that would seem to have vindicated our views

The issue hinges on whether or not the material on which feather lines are impressed, and of which a few extraneous blobs exist elsewhere on the fossil surface, is comprised of a cement which is foreign to the rock At our request the museum authorities supplied us with a sample of the suspect material and of the native rock matrix These samples have now been examined by Dr Lee M Spetner and his colleagues in Israel using a scanning electron microscope and X-ray spectroscopy The sample from the rock matrix shows a characteristic crystalline structure exactly as in other specimens of Solnhofen limestone, with identical X-ray resonance spectra But the sample from the suspect material shows a non-cystalline structure resembling that of amorphous material bound by an organic glue X-ray resonance spectra showed large amounts of silicon as well as lead and chlorine which are certainly alien to native Solnhofen limestone

These striking differences in texture and composition between the suspect regions and the native matrix are, in our view, a strong indication that this dispute will eventually be resolved in our favour The results have been communicated to the British Museum along with a request for further samples of material from the fossil for examination with a view to narrowing down the possible organic compounds that are involved in the 'glue'

The Science Critic: A Critical Analysis of the Popular Presentation of Science.
By Maurice Goldsmith *Routledge & Kegan Paul 1986 Pp 217 £15 95, $35*

It is a truism, forever fixed in our childhood minds by the story of Pandora's box, that knowledge can be used for good or ill and that the problem for human societies is to maximize the former and minimize the latter In the eighteenth century this problem was sufficiently evident to Dr Johnson, when he astounded the world by completing his book *Rasselas* within a week, to invent a philosopher who would not communicate his secret of manned flight until mankind became more virtuous

Since 1759 there have been many other authors who have espoused the argument that scientists ought to cease work and suppress their findings as soon as it is clear that damage to their fellow men might ensue I doubt if these arguments would have carried much weight in Dr Johnson's day, in a society that was largely rural and agricultural and for which the relatively feeble power of the human biped was augmented only by that of large mammals or that available from wind or falling water Johnson's younger contemporaries such as James Watt, Abraham Darby and Matthew Boulton changed this situation irreversibly by applying knowledge, largely empirically gained, to invent the steam engine and iron and steel rails and wheels The revolution they started gathered momentum over about one and a half centuries and transformed Western society into a primarily industrial and urban one

Amongst the by-products of the Industrial Revolution were Victorian self-confidence and the establishment of colleges and institutions where science, engineering and technology could be taught and advanced in the sure and certain hope that the knowledge would further mankind's power over the animate and inanimate world, then deemed to be the only route to human material progress But there was a darker side which soon became evident and was manifested by environmental pollution and consequent disease, social strain and sometimes discord, and struggles between imperialist powers for access to the cheap raw materials and the captive markets necessary to maintain growth in the manufacturing industries It is arguable that neither the Industrial Revolution nor its outcomes would have been foreseen either by those pioneers who made it possible or the nation's political leaders

Now the society created by the Industrial Revolution is giving way to another, and the engine of this change is science The principal advances in knowledge are twofold first, the powerful combination of the analysis of operations into a series of questions demanding a simple yes or no answer with the developments in solid state physics to make the micro-chip possible, and, secondly, the understanding of the control and information systems in living cells The former has led to the computer, which has greatly augmented human mental power, whilst the latter has far-reaching implications for medicine, agriculture and the efficient and cheap production of chemicals It seems likely that the judgement of history will be that this Information Revolution will be much more significant than the Industrial Revolution It certainly poses weightier questions, for the potential benefits are so much larger and so are the risks

In the twentieth century scientists have shown themselves to be aware of the dilemma which this knowledge poses for them Some, like the founding members of the American Association of Atomic Scientists 40 years or so ago, thought they must make a concerted effort to explain to the public what the implications of unlocking the power of the atomic nucleus were In so doing they were adopting the view, later articulated by Dr John Platt, that scientists should be the cartographers of the future, laying out for their fellow citizens a map of what was possible so that human societies could decide on which destinations and routes they wished to take Just over ten years ago, molecular biologists meeting at Asilomar seemingly echoed Dr Johnson's philosopher in accepting a voluntary moratorium on research in genetic engineering, a breathing space in which to consider the social implications To go the whole way with Dr Johnson would be wrong, however Quite apart from the impractibility of exercising the responsibility to suppress the findings of scientific work in a consistent way, the scientific estate, however much more knowledgeable than the rest of the population, has no right to take such decisions on behalf of society

The plain facts are that the decisions about science policy must in the end be taken as part of the normal political process and that much of the scientific enterprise of any country must be managed by the government of the day, if only because it is the main paymaster In the first chapter of his book, Dr Maurice Goldsmith tells the reader that societies will not be equipped to adopt a sensible attitude to contemporary science and scientists, let alone optimize science policy, unless there exists a body of "science critics" The science critic is defined as "a public policy journalist, alerting us to the growing pains of future worlds through the day-to-day discoveries of the present" No one would disagree with this proposition, but I doubt whether it is a sufficient as well as a necessary condition, societies are more complex than that and we know too little about their workings

Chapter 1 brings us to this conclusion via a great deal of verbiage and quotations from gurus such as C P Snow, C H Waddington, J D Bernal and Aldous Huxley Delightful they are too but quite unnecessary to the argument The remaining chapters, though less loaded with quotations, are refreshingly different They contain facts and tell us a good deal about scientific journalism, how it works, its priesthood and prizes They offer a good deal of practical advice to anyone thinking of taking up this profession and possibly, though I am in no position to judge, will be helpful to existing practitioners

The second and longest chapter is a description of how the various media operate in the Western world, and will repay attention by scientists who so often fail to get their message across and to understand the adaptations they must make to be successful in communicating to the public There follows a brief essay on science fiction, a subject in which I could never be interested, because it seemed to me that science itself was so much more interesting and called for much greater leaps of imagination Next there are two succinct essays on school science education (largely in Britain) and on how the message may be handled in a Third World country I greatly enjoyed both of them, the first because I knew something about the subject, the second because I did not and the confidence engendered by the sound and balanced presentation of the first spilled over and gave me confidence that the second must be of similar quality

Finally Dr Goldsmith returns to his new breed of animal, the science critic, whom he sees not just as a reporter of science but as someone who makes value judgements about it and its place in society But to do so such a person would have to be equipped with a broad synoptic view of science, be able to see the future and discern similarities, and be able to interpret and communicate science and uphold its integrity I could not but help feel that this chapter described the remarkable science teacher I had at school 60 years ago, which in turn made me consider the problem of generating a supply of such remarkable people to perform this necessary function This is briefly touched on by Dr Goldsmith, but I am sure he would be the first to admit that the time when we shall have an adequate supply of these critic-communicators is far distant The remaining 60 per cent of the book consists of two appendices, the first of which is concerned with some of the nuts and bolts of science journalism, and the second with examples of popular science writing

I enjoyed reading this book and I think many others would too The trouble is that it touches upon many topics, none of which is explored in any depth, and the main conclusions seem to be so miniscule Glancing at it again after my first reading, it seems to me that it was probably written, if not in Dr Johnson's record-breaking time, then very quickly from pieces that had already been published or were lying about nearly finished on the author's desk No criticism of Dr Goldsmith for that, but merely to say that whilst it is a good read it is not a great book ☐

Lord Dainton is Chancellor of the University of Sheffield, Sheffield S10 2TN, UK, and was, among other appointments, formerly President of the Association for Science Education and Chairman of the British Library Board

Going into a trance

Anthony W Clare

The Induction of Hypnosis. By William E Edmonston, Jr *Wiley 1986 Pp 432 £42 25, $43 95*

THERE are those, most notably Leon Chertok, who argue that the therapeutic element in psychoanalysis, in so far as there is one, is suggestibility, and that psychoanalysis, through its intermediary the transference, has not disengaged from hypnosis but has merely changed the terminology Freud himself declared in 1921 that "we still have no explanation of the nature of suggestion itself, that is to say of the conditions in which one is subject to its influence" It is indeed the case that ever since then many analysts have retained a lively interest in the subject of hypnosis

Contemporary hypnotists stress the importance of eye fixation and the attention-rivetting techniques employed to bring about the hypnotic state They do so with the same degree of purist vigour as analysts emphasize the crucial importance of free association and interpretation, and behaviourists insist on the essential therapeutic features of conditioning and deconditioning The real question, however, is the emotional aspects of the therapeutic relationship, the affective content of the procedures rather than the actual theoretical procedures themselves, yet it is this affective component of therapy, bound up as it is in notions such as suggestibility and susceptibility, which is poorly studied and indeed rarely considered

The fact remains that it was the nineteenth-century developments in hypnotherapy that facilitated the growth of modern psychotherapy, and it does not seem too far-fetched to believe that in the unravelling of hypnosis lies the answer to the thorny question of the efficacy of psychotherapeutic procedures in general Such issues are not the subject matter of Edmonston's book any more than they seem to be the concern of many psychotherapists But the contents of the book make it abundantly plain that such a state of affairs cannot last

If the author of this detailed text on the subject is to be believed, the history of hypnotic induction is the history of medicine It is true that the induction of sleep has been a mainstay of therapeutic interventions since before Hippocrates References to what sound like hypnotic trance states can be found in Vedic medicine, in the Papyrus Ebers of Egyptian medicine fifteen centuries before Christ and in the healing rituals of the Irish Druids before the arrival of St Patrick Not surprisingly, in the revised history of hypnosis Mesmer ceases to be the pivotal figure he seemed and is deemed to be not so much a pioneer as a catalyst, giving hypnosis a vital nudge forward at an opportune time

Edmonston devotes a great deal of space to a historical review of the role of hypnosis and to an enumeration of the many, varied and elaborate ways of inducing a hypnotic trance But at times the list of treatments falling under the rubric of hypnosis becomes rather elastic It is doubtful, for example, that the methods of Valentine Greatrakes, a contemporary of William Harvey, were truly hypnotic, given that he relied upon the laying on of hands and the smearing of his patients at St Bartholomew's Hospital with spittle!

The real issue in contemporary hypnosis is not its historical roots, nor its induction methods It is the precise relationship between classical hypnosis, with its emphasis on the induction of a trance or sleep-like state, and the newer task-orientated forms of behaviour therapy with their emphasis on relaxation, concentration, the relief of anxiety and the induction of tranquillity A related question is to do with the relationship between the analytic transference, so stressed within psychodynamic psychotherapy, and the notion of suggestibility which lies at the heart of hypnotic methods These, however, are matters that are scarcely touched upon in this book ☐

Our lady of radium

H W Paul

Marie Curie: A Life. By Françoise Giroud Translated by Lydia Davis *Holmes & Meier, New York 1986 Pp 291 $34 50*

ROENTGEN'S discovery of X rays in 1895 led directly to the discovery of radioactivity by Henri Becquerel Unlike X rays, radioactivity did not excite scientists or the public, no lead-lined knickers were sold to protect prudent women from its scrutiny Then, in 1898, Marie and Pierre Curie announced their discovery of polonium and radium, and a radium craze soon infected the world The public had not been so interested in science since the publication in 1859 of Darwin's book on the origin of species

Maria ("Manyad") Sklodowska, a polyglot positivistic Pole from Warsaw, went to the University of Paris in 1891 to study science Polish nirvana freedom from the Russian yoke, cheap education, even for women, the opportunity to work for the improvement of mankind through science, and freedom to discuss the Polish condition without the threat of arrest Marie was a brilliant student and immediately attracted the attention of Sorbonnard mandarins such as Paul Appell, Edmond Bouty and Gabriel Lippmann

In 1895 she married into the tribe of French physicists, a rather inbred group The marriage changed Pierre Curie's career, for he was seduced into collaborating with Marie on the scientific obsession of the day, radioactivity Working in a shed at the municipal school of industrial physics and chemistry, they made their famous discoveries International fame led to success in Paris Pierre was given a chair at the Sorbonne, to prevent his going to Geneva, and after his death in 1906 the chair went to Marie The science faculty's radical precedent of opening its ranks to women was not followed by the Académie des Sciences, which narrowly preferred physicist Edouard Branly of the Institut Catholique — a minor triumph for Catholicism over republicanism Nearly a century before, women interested in science had been excluded from the newly-created faculty on the grounds that men would be more interested in them than in the professors' lectures That must rank as one of the world'ss worst academic administrative decisions In her long career Marie Curie won two Nobel prizes, one, with Becquerel and Pierre, in physics, and one for herself alone in chemistry Amongst the many virtues of the Third Republic (1871–1940) was that it made possible, if improbable, a career in science for women

In this book, Françoise Giroud has given us a very touching portrait of Marie

Curie. The history of science is sometimes handled cavalierly and the political passages are no better: Bismarck's Polish policy is reduced to a misleading *boutade*, and Prussia is generously given five million instead of two-and-a-half million Poles. Yet there is a great deal of reliable information on science artfully woven into the biography.

Madame Giroud often goes to the heart of matters with rare skill. The cultural and especially the social contexts are also deftly sketched, with emphasis on the economic exploitation of women. Glimpses into the private lives of the austere Curies and their more sybaritic colleagues provide some relief from Marie's grim devotion to science. But Marie Curie is not famous because she knew Paderewski or visited Rodin's studio, or even for her love affair with Paul Langevin which is treated in exquisite detail by Madame Giroud. Langevin's wife made the scandal notoriously public, and Paul Appell, the desperate dean of the faculty of sciences, wanted to solve matters by encouraging Marie to return to Warsaw. The American physicist B.B. Boltwood, a collaborator of Rutherford's, was satisfied that he had been correct in classifying her as a detestable idiot, but generous American support for Marie's work indicates that his opinion was not widely held in the United States.

The work of the Curies gave French science an international attention it had not enjoyed since the national orchestration of Pasteur's genius. The glory was equally deserved, and dozens of foreign researchers came to work on radioactivity at the Radium Institute in the Latin Quarter's vast city of science. In 1925 Marie picked Fred Joliot as her laboratory assistant, and his subsequent marriage to her scientist daughter Irene produced another great team in French physics. Joliot went on to become the main figure in the development of nuclear energy in France. Nearly up to her death in 1934 Marie was a tireless international ambassador for French science and an effective propagandist at home, where Jean Perrin and his friends were preparing the ground for the post Second World War structures and functions of French science.

Mary Evans

In collaboration — Marie and Pierre Curie.

Madame Giroud's book is heavily dependent on works such as Eve Curie's study of her mother. But its dramatic style and theme of *Une Femme Honorable* (the French title) make it a satisfying night's reading. ☐

Optimal ideas

Brian Charlesworth

Physiological Ecology of Animals: An Evolutionary Approach. By R.M. Sibly and P. Calow. *Blackwell Scientific: 1986. Pp.179. Hbk £26, $49; pbk £11.95, $24.50.*

OVER the past decade, the quantitative application of the concept that the properties of living organisms represent optimal solutions to specific design problems has been a growth industry. Richard Sibly and Peter Calow have been prominent exponents of this approach, and the aim of this book is to set out some principles of optimization theory, and to apply them to a series of problems in physiological ecology and life-history evolution. The basic procedure is to assume a plausible set of constraints acting upon the properties of interest in the particular study, for example that an increase in the amount of effort devoted to reproduction at a given stage of the life-cycle leads to a decrease in the chance of survival to the next stage. Given a criterion by which to measure darwinian fitness, one then calculates the set of values of the properties that yield a maximum in fitness according to the specified constraints. It is then assumed that natural selection will have caused populations of organisms to evolve close to this optimal set. Their observed properties are compared with the predictions of the model, in an effort to test the model's validity.

This procedure is often criticized on the grounds that failure of an optimization model to fit the real world does not provoke its originator to abandon belief in natural selection as the main force guiding the evolution of the characteristics of interest; rather, it usually leads him to tinker with the details of the model. This criticism is somewhat misplaced, because the aim of workers using these methods is not to test the general validity of the theory of natural selection, but to uncover the biological factors which may be of significance in moulding the action of selection on the traits in question. Furthermore, given the complexity of biological systems one would have to be wildly optimistic to expect an accurate fit between predicted and observed properties. So emphasis has often been placed on theoretical predictions of the consequences of variation in ecologically determined factors which modulate the ways in which the system responds to selection, and on comparisons of populations with appropriate differences in ecology to see if they differ (at least qualitatively) in the expected fashion. Thus, it is a stock-in-trade of life-history theory that species living in environments with high adult survival relative to juvenile survival should invest less in reproductive effort per breeding season, compared with otherwise similar species with low adult survival.

Sibly and Calow bring out these principles in a number of case studies, ranging from an analysis of the factors affecting the efficiency of guts, to strategies of growth and reproduction. The emphasis is on the development of optimization models, rather than detailed testing against the data; indeed they state that their aim is to stimulate experimentalists to provide the necessary data. They succeed in convincing one of the diversity of topics to which their approach can be applied, and the book will be of considerable use to biologists in this area.

The authors can, however, be criticized on several points. One is that they give little indication of previous contributions to life-history theory, a relatively mature area of enquiry. Instead, they present their own reformulations of classic models as though they were wholly original, and provide only scanty citation of the literature. This will not help beginners find their way. More importantly, they fail to mention alternatives to optimization methods. Thus, there is no reference to Williams's and Medawar's theories of senescence, which have an important bearing on life-history evolution. Little mention is made of the possible role of competition in moulding selection on growth and size, and Maynard Smith's Evolutionarily Stable Strategy method for handling the complications that arise in competitive situations is not discussed. While the authors' approach has considerable value, and they have every right to advocate it, their book cannot be said to offer a comprehensive survey of the methods needed to solve problems in evolutionary ecology. ☐

Steps out of time

Eric Ashby

Walkers. By Miles Jebb. *Constable, London: 1986. Pp.202. £10.95.*

SIXTY years ago, devotees of the non-fiction book at bedtime were well supplied by a genre which is now rare: the essay. Contemporaries of Chesterton, Belloc and Aldous Huxley had plenty of entertainment awaiting them at the end of the day. Today there are very few competent practitioners in that style of writing. One can still enjoy the classical essayists — Charles Lamb for the light-hearted, Emerson for the sober-minded, and Montaigne and Bacon — but who is writing in that style now?

Well, Miles Jebb for one. His book, *Walkers*, is in the tradition of the whimsical nineteenth-century essayists. In eleven brief chapters Jebb writes about the various kinds of people who walk or have walked: pilgrims, athletes, intellectuals, tramps, ramblers... I'll not disclose the whole list. The book is a compilation of anecdotes and episodes from history and fiction, told with the comfortable informality of after-dinner conversation, by a man with a well-stocked mind.

If you start to delve into the literature about walking, it is surprising what turns up. Each of Jebb's eleven kinds of walker finds himself heir to certain conventions. The value of a pilgrimage may be enhanced by discomfort: "The Countess of Clare threw away her shoes as she started on a pilgrimage". Athlete–walkers are out to break records: Sean Maguire, who "in 1978 walked the 7327 miles from Yukon to Florida in three hundred and seven days"; and Sebastian Snow, who reckoned he had taken some 11,745,000 paces in his walk from the tip of South America to Panama City with a 60 lb pack on his back. Intellectual walkers are the most articulate (witness Hilaire Belloc's *Path to Rome*) and they often philosophize as they walk. Or they boast of a kind of muscular intellectualism: thus Leslie Stephen, when at Cambridge, walked to London (over 50 miles) in 12 hours to attend a dinner of the Alpine Club.

Tramps fall into two categories: those who walk because they have nowhere else to go, and those who "walk away from convention". The former are inarticulate (though the poet W.H. Davies was an exception); the latter, such as Stevenson and Maxim Gorky, often become tramps in order to collect material for writing. Ramblers not only ramble; they combine to form pressure groups to lobby for conservation, and they sometimes flock together in group walking. They are somewhat querulous, having been driven off the roads by traffic, but we are indebted to them for their lobbying: in the United States, the Sierra Club has a fine record in defending the wilderness, and in Britain the Ramblers' Association has preserved many footpaths that would otherwise have been obliterated by farmers.

If you like erudite and genial conversation about themes such as these, this is a bedtime book to savour. ☐

Thought of biology

P. T. Saunders

Biophilosophy: Analytic and Holistic Perspectives. By Rolf Sattler. *Springer-Verlag: 1986. Pp.284. Pbk DM66*

ROLF Sattler is a biologist who believes that it is important to understand the fundamental presuppositions of biology and how they influence research and even our view of life itself. In *Biophilosophy* he sets out to introduce other biologists to these ideas.

I am in full sympathy with Sattler's aim, and he has gone some way towards achieving it. But there are reservations. The book seems to be intended as both an introductory text and a monograph, and rather falls between the two stools. Far too much material has been crammed into a text that also has to include elementary expositions of basic ideas. As a result, some explanations are marred by what are, for the beginner, digressions. At other times, Sattler rushes along at great speed; he deals with the issue of free will in just over a page. Many terms and ideas are mentioned so fleetingly that the reader not only is left uninformed about them but will not even be able to grasp how they are relevant to the discussion.

Often Sattler does no more than mention that a certain idea has been put forward and give some references. For example, he considers that the idea of species as individuals rather than classes leads to the scientific view of unity or oneness to which he devotes the last chapter. Yet he says very little in support of the idea, beyond mentioning the common gene pool and providing some references to "a critical appraisal" of the concept. It would have been better to spend more time on those questions that he considers to be most important, and to compensate by omitting some other material altogether.

Biophilosophy, then, is not a satisfying book. The author seems to have tried to get down in print everything he has thought about, from plant morphology to Zen Buddhism. Further, aspects of the selection of material and the relative emphasis given to different topics mean that he has not fully assimilated all that he has learned into a coherent whole. On the other hand, if *Biophilosophy* loses by not having been written by a professional philosopher, it also gains from having been written by a working scientist to whom these ideas matter, and who sees many of the issues from the same point of view as his readers.

Far too few biologists are aware of the philosophical issues that underlie and influence what they do. Moreover, because so much of the philosophy of science is concerned with physics, not biology, it is not readily accessible to them. Biologists who read this book will become acquainted with many important questions, and, what is more, will have them explained in familiar terms — there are not many introductions to the philosophy of science that illustrate the basic concepts through plant morphology, instead of quantum mechanics. I even approve of reminding the reader that plant morphology and Zen Buddhism are both worth thinking about, and not necessarily in separate intellectual compartments. I only wish Sattler had tightened the whole thing up a bit. ☐

CONVENIENT·INFORMATIVE·TIMELY·PROVOCATIVE

FOUR DYNAMITE REASONS WHY YOU SHOULD SUBSCRIBE TO BIO/TECHNOLOGY NOW . . .

1. You'll save time. Because you don't have time to read every journal in the field, BIO/TECHNOLOGY is written and edited to give you all the information you need in ONE convenient source. BIO/TECHNOLOGY is the only journal to give you news. Features. Original research. Product evaluations. Industrial applications. Job openings. Book and product reviews. And more. If it's important to your work, you'll find it between the covers of BIO/TECHNOLOGY.

2. You'll learn new ways to improve your on-the-job skills and run a more successful operation. Each month BIO/TECHNOLOGY gives you the scoop on invaluable start-up information . . . the latest instrumentation . . . marketing breakthroughs . . . funding sources . . . new technologies . . . patents and licences . . . profiles on how others are avoiding the pitfalls and reaping the rewards. In fact, just one practical tip from BIO/TECHNOLOGY can be worth many times the cost of your subscription.

3. You'll be up-to-date on all major industry developments. With correspondents all over the world, BIO/TECHNOLOGY delivers the inside story on who's doing what, where. You'll get the latest word on changing government regulations and tax law, and how they affect your work.

Plus you'll read original research papers by bench scientists, engineers, and biologists that will help keep you in the forefront of every new discovery worth knowing about.

4. You'll get new ideas you can put to use immediately. BIO/TECHNOLOGY lets you rub elbows with eminent scientists, tour new facilities and learn how new processes work in every field from genetic engineering to molecular biology. Each month, BIO/TECHNOLOGY helps spark ideas for your own research, for new industrial applications and for getting along in the increasingly competitive financial arena.

If you're not already subscribing to BIO/TECHNOLOGY, don't delay the moment any longer - return the coupon below and we will send you twelve issues. You risk nothing. If for any reason BIO/TECHNOLOGY doesn't live up to your highest expectations, just let us know and you'll receive a full refund on all unmailed copies. Remember too, that your subscription may be tax deductible.

TO START RECEIVING YOUR SUBSCRIPTION, FILL OUT THE COUPON BELOW AND RETURN WITH PAYMENT TO:

Forty years of genetic recombination in bacteria

Between April and June 1946, Joshua Lederberg and Edward L. Tatum carried out a series of experiments that proved that bacteria can exchange their genes by sexual crossings. The experiments were reported in Nature *just 40 years ago[1]. In the following pair of articles, Joshua Lederberg first provides a personal reminiscence of the circumstances of the discovery and then, together with Harriet Zuckerman, considers it as a possible case of 'postmature' scientific discovery.*

A fortieth anniversary reminiscence

Joshua Lederberg

In September 1941, when I started as an undergraduate at Columbia University, the genetics of bacteria was still a no-man's-land between the disciplines of genetics and (medical) bacteriology. The question whether "bacteria have genes, like all other organisms" was still unanswered, indeed rarely asked. My own thoughts at that moment lay elsewhere. I looked forward to a career in medical research applying chemical analysis to problems like cancer and the malfunctions of the brain. Cytotoxicology then appeared to be the most promising approach to cell biochemistry. It was Frances J. Ryan (d. 1963) who turned my attention to the sharper tools of genetics.

Ryan had spent 1941–42 as a postdoctoral fellow at Stanford University, where he had met G. W. Beadle and E. L. Tatum (d. 1975), and had become fascinated with their recent invention of nutritional mutations in *Neurospora* as a tool for biochemical genetic analysis[2]. Although working on a fungus like *Neurospora* did not go down smoothly in a Department of Zoology as at Columbia, where Ryan had accepted an instructorship, he established a laboratory to continue these studies. In January 1943 I was fortunate to get a job in his laboratory assisting in the preparation of media and handling of *Neurospora* cultures. Ryan's personal qualities as a teacher and the setting of serious research, discussion with him, other faculty members and graduate students in the department nourished my education as a scientist. On 1 July 1943, I was called to active duty in the United States Naval Reserve, and my further months at Columbia College alternated with spells of duty at the United States Naval Hospital, St Albans, Long Island. There, in the clinical parasitology laboratory, I had abundant opportunity to observe the life cycle of *Plasmodium viva*. This experience dramatized the sexual stages of the malaria parasite, which undoubtedly sensitized me to the possibility of cryptic sexual stages in other microbes (perhaps even bacteria). In October 1944, I was reassigned to begin my studies at Columbia Medical School; but I continued working with Ryan at the Morningside Heights campus.

Lederberg in 1945

Discovery

The important biological discovery of that year, by Avery, MacLeod and McCarty, was the identification of DNA as the substance responsible for the *Pneumococcus* tranformation[3]. This phenomenon could be viewed as the transmission of a gene from one bacterial cell to another; but such an interpretation was inevitably clouded by the obscure understanding of bacterial genetics at the time. Avery's work, at the Rockefeller Institute in New York, was promptly communicated to Columbia biologists by Theodosius Dobzhansky (who visited Rockefeller) and by Alfred Mirsky (of the Rockefeller faculty) who was a close collaborator of Arthur Pollister in the Zoology Department. The work was the focus of widespread and critical discussion among the faculty and students. Mirsky was a vocal critic of the purported chemical identification of the transforming agent, while applauding the central importance of the work. For my own part, the transcendent leap was simply the feasibility of knowing the chemistry of the gene. Whether this was DNA or protein would certainly be clarified quickly, provided the *Pneumococcus* transformation could be securely retained within the conceptual domain of gene transmission. I read the Avery, MacLeod and McCarty paper on 20 January 1945, prompted by Harriett Taylor (later Ephrussi-Taylor) a graduate student in Zoology who planned to pursue her postdoctoral studies with Avery. My excited response is recorded as ... "unlimited in its implications... Direct demonstration of the multiplication of transforming factor... Viruses are gene-type compounds."

At once, I thought of attempting similar transformations by DNA *in Neurospora*. This organism had a well understood lifecycle and genetic structure. The biochemical mutants opened up by Beadle and Tatum also allowed the efficient detection of nutrionally self-sufficient (prototrophic) forms, even if these were vanishingly rare. This would facilitate the assay of transformational events.

Between January and May, 1945, I shared this idea with Francis Ryan; in June, he invited me to work on the subject with him. To our dismay, we soon discovered that the leucine-minus *Neurospora* mutant would spontaneously revert to prototrophy[4], leaving us with no reliable assay for the effect of DNA in mediating genetic change in *Neurospora*. Questions about the biology of transformation would remain inaccessible to conventional genetic analysis if bacteria lacked a sexual stage. But was it true that bacteria were asexual? Rene Dubos' monograph, *The Bacterial Cell*[5], footnoted how inconclusive the claims were for or against any morphological exhibition of sexual union between bacterial cells.

My notes dated 8 July 1945 detail hypothetical experiments both to search for mating among *Monilia* (medically important yeast-like fungi) and to seek genetic recombination in bacteria (by the protocol that later proved to be successful). These notes coincide with the beginning of my course in medical bacteriology. They were provoked by the contrast of the traditional teaching that bacteria were *Schizomycetes*, asexual primitive plants, with an appreciation of sexuality in yeast[6], which was represented at Columbia by the graduate research work of Sol Spiegelman and Harriett Taylor.

Dubos[5] cited many unclear, and two clear-cut negative results[7,8] for sexuality in bacteria using genetic exchange methodology. But these two studies had no selective method for the detection of recombination and so would have overlooked the process had it occurred less often than perhaps once per thousand cells. With the use of a pair of nutritional mutants, say A^+B^- and A^-B^+, one could plate out innumerable cells in a selective medium and find a single A^+B^+ recombinant. In early July, I began experiments along these lines. In the first instance I used a set of biochemical mutants in *Escherichia coli*, which I began to accumulate in Ryan's laboratory. To avoid the difficulty that had arisen in our *Neurospora* experiments, a spontaneous reversion from A^-B^+ to A^+B^+, the strategy would be to use a pair of double mutants: $A^-B^-C^+D^+$ and $A^+B^+C^-D^-$. Sexual crossing should still generate $A^+B^+C^+D^+$ prototroph recombinants. These would be unlikely to arise by spontaneous reversions which, in theory, requires the coincidence of two rare events; $A^- \rightarrow A^+$ and $B^- \rightarrow B^+$. Much effort was devoted to control experiments to show that double reversions would follow this model, and so occur at a negligible frequency in the cultures handled separately. Thus the occurrence of prototrophs in the mixed cultures would be presumptive evidence of genetic recombination.

Long shot

Meanwhile at Stanford, Ed Tatum, whose doctoral training at Wisconsin had been in the biochemistry of bacteria, was returning to bacteria as experimental subjects, having published two papers on the production of biochemical mutants in *E. coli*[9], including double mutants like those described here. During the summer of 1945 Francis Ryan learned that Tatum was leaving Stanford to set up a new programme in microbiology at Yale. He suggested that, rather than merely ask Tatum to share these new strains, I apply to work with him and get the further benefit of his detailed experience and general wisdom. Tatum agreed and suggested that I arrive in New Haven in late March, to give him time to set up his laboratory. He hinted that he had some similar ideas of his own, but never elaborated them. The arrangement suited him by leaving him free to complete his work on the biochemistry of *Neurospora*, perform the heavy administrative duties of his new programme, and still participate in the long-shot gamble of looking for bacterial sex.

Experimental luck

1. We have learned[12] that *E. coli* strain K-12 itself was a remarkably lucky choice of experimental material: only about one in twenty randomly chosen strains of *E. coli* would have given positive results in experiments designed according to our protocols. In particular, strain B, which has become the standard material for work on bacteriophage, would have been stubbornly unfruitful. Tatum had acquired K-12 from the routine stock culture collection in Stanford's microbiology department when he sought an *E. coli* strain to use as a source of tryptophanase in work on tryptophan synthesis in *Neurospora*[13]. The same strain was then in hand when he set out to make single, and then double mutants in *E. coli*[9]. In 1946, I was very much aware of strain specificities and was speculating about mating types (as in *Neurospora*). I have no way to say how many other strains would have been tried, or in how many combinations, had the June 1946 experiments not been successful.

2. An equally important piece of luck was that, the selected markers Thr (threonine) and Leu (leucine) are found almost at the origin of the *E. coli* chromosome map[14]. The cognoscenti will recognize that in a cross $B^-M^-T^+L^+F^+ \times B^+M^+T^-L^-F^-$, the configuration used in June 1946, these chromosome localizations offer almost a maximum yield of selectible recombinants. We were therefore led stepwise into the complexities of mapping.

It took about six weeks, from the first serious efforts at crossing in mid-April 1946, to establish well-controlled, positive results. These experiments could be done overnight, so the month of June allowed over a dozen repetitions, and the recruitment of almost a dozen genetic markers in different crosses. Besides the appearance of $A^+B^+C^+D^+$ prototrophs, it was important to show that additional unselected markers in the parent stocks would segregate and recombine freely in the prototrophic progeny. This result left little doubt as to the interpretation of the experiments.

An immediate opportunity for public announcement presented itself at the international Cold Spring Harbor Symposium in July. This was dedicated to the genetics of microorganisms, signalling the postwar resumption of major research in a field that had been invigorated by the new discoveries with *Neurospora*, phage, and the role of DNA in the *Pneumococcus* transformation. Tatum was already scheduled to talk about his work on *Neurospora*. We were granted a last-minute improvisation in the schedule to permit a brief discussion of our new results.

The discussion was lively. The most principled criticism came from Andre Lwoff who worried about cross-feeding of nutrients between the two strains without their having in fact exchanged genetic information. Having taken great pains to control this possibility, I felt that the indirect genetic evidence was quite conclusive. Fortunately, Max Zelle mediated the debate, and generously offered to advise and assist me in the direct isolation of single cells under the microscope. These subsequent observations did quiet remaining concerns of the group that Lwoff had assembled at the Pasteur Institute, including Jacques Monod, Francois Jacob and Elie Wollman, who were to make the most extraordinary contributions to the further development of the field. The single cell methods were also useful in later investigations in several fields. A direct result of the Cold Spring Harbor meeting was the prompt ventilation of all the controversial issues. With a few understandable, but minor points of resistance, genetic recombination in bacteria was soon incorporated into the mainstream of the burgeoning research in molecular biology, and after another decade or so into the standard texts of bacteriology. It still took some years to work out the intimate details of crossing in *E. coli*; some, including the crucial question of the physical mechanism of DNA transfer between mating cells, are still obscure.

The public image of the scientific fraternity today has seldom been so problematic and the system cannot avoid putting a high premium on competition and self-assertion. We can recall with gratification how the personalities of Ryan[10] and Tatum[11] exemplified norms of nurture, dignity, respect for others, and above all a regard for the advance of knowledge.

Joshua Lederberg is at the Rockefeller University, New York, New York 10021. The research summarized in this article was supported in 1946 by a fellowship of the Jane Coffin Childs Fund for Medical Research.

Postmature scientific discovery?

Harriet Zuckerman and Joshua Lederberg

NEW scientific discoveries do not always flow directly from those made just before Rather, several varieties of discontinuity can be identified in the growth of science Premature discoveries are those that scientists do not attend to in a timely way, and are retrospectively described as having been "ahead of their time" These have been examined by Barber[1] and Stent[2] Here, we suggest that there are also postmature discoveries, those which, are judged retrospectively to have been 'delayed' We analyse the arguments that the discovery of bacterial sex was postmature and take up the correlative questions of how the problem was identified, and why Lederberg and Tatum[3,4] were likely candidates for making it when they did

This paper draws on documents, published and private, and analyses by the sociologist-observer and the scientist-participant Our dialectic procedure departs from most oral histories[5,6], first, the procedure was iterative as new discussion raised further possibilities, we both searched for relevant documentation, and second, we both identified the underlying analytic questions and articulated tentative answers to them We felt that personal reminiscence had to be validated by contemporary documents and other testimony as oral history and autobiography are prone to "unconscious falsification"[7]

Continuities and discontinuities

Scientific growth, usually broadly incremental, can at important times be episodic and discontinuous Premature discoveries, one conspicuous form of temporal discontinuity in science, are either passively neglected or actively resisted at the time they are made Mendel's discovery of particulate inheritance in 1865, lost to view for thirty-five years, is the best-known historical case Discoveries can be premature because they are conceptually misconnected with 'canonical knowledge'[2], are made by an obscure discoverer, published in an obscure place, or are incompatible with prevailing religious and political doctrine Barriers between disciplines imposed by specialization of inquiry also contribute to neglect or resistance[1,8-10] Although the character and sources of premature discoveries have received some analytical attention[8,11], the pattern of postmature discoveries has not been identified, much less systematically studied

For a discovery to qualify as postmature, for it to evoke surprise from the pertinent scientific community that it was not made earlier, it must have three attributes In retrospect, it must be judged to have been technically achievable at an earlier time with methods then available It must be judged to have been understandable, capable of being expressed in terms comprehensive to working scientists at the time, and its implications must have been capable of having been appreciated

Both prematurity and postmaturity can be recognized only by retrospection They differ in that prematurity is a matter of actual historical observation while postmaturity is a matter of retrospective conjecture Such formulations would seem to smack of 'Whig History', the inclination, according to Butterfield, "to produce a story which is the ratification if not the glorification of the present"[12] But, they are designed to serve quite the contrary purpose The ideas of premature and postmature discovery provide convenient handles for analysing discontinuities in the growth of scientific knowledge, and support a nonlinear and complex model of advancement in scientific understanding

Postmature discoveries are not all of a piece One class results from pre-emption of scientists' research attention For example, Linus Pauling observed that there was "no reason why" he, himself, could not have discovered the alpha helix eleven years earlier than he actually did "after a few hours of work" In fact, he was preoccupied in the interval by other seemingly more important and feasible inquiries[13,14] Another class of postmature discoveries answer questions not previously recognized by scientists to be problematic Certain assumptions, beliefs and images[15] which are also indispensable for the organization of scientific thought can, in specific cases, impede perception of lines of inquiry For example Weinberg notes that physicists neglected to pursue quantum field theory further in the 1930s because prevailing images, conceptual schemes and attitudes toward theory and empirical evidence stood in the way[16] In our case study, both cognitive and social processes obstructed the thinking of scientists about recombination in bacteria

Sources of neglect

Why was recombination in bacteria not perceived as problematic before 1946? How had asexuality in bacteria come to be an unquestioned 'truth' and how was that view perpetuated?

Before 1870, many believed that the different shapes bacteria assumed were varieties of the same organism, which changed under varying conditions Indeed, the doctrine of polymorphism or bacterial plasticity became the basis for extravagant claims about variability through most of the nineteenth century By 1872, Ferdinand Cohn concluded that the various shapes bacteria took were not different forms of the same organism, they were monomorphic and did not change during their short lifetimes[17] Yet reports of variation continued until 1881 when Robert Koch introduced a simple and effective means for growing pure cultures Koch's pure-culture method, which became a symbol of modern bacteriology with its phobia of contamination, together with Cohn's doctrine of monomorphism rapidly changed bacteriologists' views about variation The two were consolidated into what was called the Cohn–Koch Dogma, which discouraged for years the study of the problems of morphology, inheritance and variation in bacteria[18]

Cohn was convinced that bacteria were primitive plants which could "only reproduce by asexual means" and in 1875 characterized all bacteria as *Schizomycetes* or 'fission fungi' With every use of that label, bacteriologists were reminded that these organisms reproduced only by fission and that they were simple primitive plants, a tradition that had begun with Leeuwenhoek's first observation of bacteria in 1675 Labels, categories, nomenclature and taxonomies usually help to organize scientific thought but can also delay the reexamination of fallacious traditions, thus becoming self-fulfilling prophecies[19] In the end, the emergence of medical microbiology as a science depended on the doctrinal base laid down by Cohn and the pure culture methods of Koch Nonetheless, monomorphic doctrine, when strictly construed, threw out the baby of bacterial variation with the dirty bath water of contamination It was widely assumed that observations of bacterial variation had to result from contamination Bacteriologists took experiments involving variation to be error-prone and disreputable[20] Such experiments were to be avoided as having great procedural difficulty and little intellectual merit With the strong incentives in science for avoiding problems notorious for leading to irreproducible results, very few scientists would elect to undertake them

Bacteria occupied an ambiguous place in the hierarchy of living organisms To many, these organisms appeared so primitive that they could not yet have evolved 'differentiated genes' This image also reinforced the use of bacteria as exemplars of pre-genic levels of organization for physico-chemical analysis Once such complex imagery becomes established, special provocation is needed to splinter away one or more of its elements

Disciplinary emphases and the division

of labour among the sciences also diverted attention from the problem of bacterial sexuality. Bacteriologists were principally concerned with problems in medical pathology rather than issues like the biology of bacterial reproduction. Geneticists were no more interested in bacterial reproduction than bacteriologists. They were occupied with larger organisms in which the products of crossing were readily observed. Thus, disciplinary division of labour and the careful choice of organisms for inquiry, both generally conducive to the development of scientific knowledge, contributed in this instance to neglect of bacterial recombination. It has been argued, however, that 'disciplinary dogmatism' and 'disciplinary monopoly' have only rarely impeded the development and diffusion of scientific innovation[21].

Members of the Delft School of Microbiology, in the early part of this century, did bridge the gap between bacteriology and genetics. Clearly separating themselves from the medical bacteriologists who maligned bacteria, they believed that progress in fundamental microbiology depended on people who 'loved' microbes[22]. Martinus Beijerinck, the main figure in the group, seems now to have been the most likely candidate for investigating bacterial sex. He rejected prevailing dogma on bacterial invariability, promptly sited deVries' finding on plant mutations and offered some of the first coherent challenges to strict monomorphism[23]. He also developed 'enrichment culture' methods, forerunners of the selective techniques used later in discovering bacterial recombination. Moreover, he was better informed than most microbiologists about work on plant hybridization which would have been useful in planning any investigation of sex in bacteria. Beijerinck and the Delft School were likely candidates for investigating bacterial sex, but they did not. In fact, Beijerinck strongly supported the Cohnian dogma of Schizomycetes. Thus the problem of sexual recombination still fell between disciplinary schools[24].

Significance of bacterial sex

By the 1930s, developments were under way that led biologists to reexamine how bacteria related to other forms of life and whether bacteria really had genes. Important among these developments was the unification in biological thought of Mendelian genetics, quantitative population theory and darwinian evolution, particularly the notion of species being Mendelian breeding populations or isolated gene pools. The idea that sexuality was, itself, an evolved genetic system proved particularly provocative, with illustrations drawn from simple and complex plant life. Dobzhansky's monograph, "*Genetics and the Origin of Species*"[25], was widely read as the definitive reinterpretation of darwinian theory of evolution and focused interest on the details of breeding systems as the key to understanding evolutionary development. This, in turn, sharpened interest in understanding the evolution of organisms, like bacteria, believed to be devoid of sexual mechanisms.

The biochemical analysis of microbial nutrition, especially by Knight and Lwoff[18], was another major impetus to reexamining the relationship of bacteria to other forms of life. In particular, the discoveries that the biochemistry of microbes paralleled in many details that of higher organisms inspired Beadle and Tatum's work on *Neurospora* in 1941[26]. They showed *Neurospora's* usefulness as a research material for studying the genetic control of an organism's development through the encoding of specific enzymes, known as the 'one-gene-one-enzyme' hypothesis. This marriage of biochemistry and genetics and particular significance for the Lederberg–Tatum work[27,28].

There was also renewed speculative interest in a biochemical theory of the origin of life. "*The Origin of Life on Earth*"[29] by the Russian biochemist, Oparin, became available in English in 1944, as did "*What is Life?*"[30] by the physicst, Schrodinger. Both focused attention on questions that demanded the integration of the biology of viruses and microbes with the more traditional biology of plants and animals.

The connections between these independent developments were not always apparent at the time. But one event did call attention to their common message, the discovery by Avery, MacLeod and McCarty in 1944 which identified DNA as the transforming principle that changed rough non-pathogenic pneumococci into smooth virulent ones.

The scientific significance of that discovery has been examined in detail[32-38]. For our purposes, it highlighted two important questions: what was the structure of bacterial genes and how were they transferred? Thus the work by Avery *et al* made the question of bacterial sex newly consequential. Dubos[39] makes it clear that had sexual reproduction been observed, it would have been understood and appreciated. But bacteria were so widely assumed not to reproduce sexually that noone considered this problem to be important. Dogma prevailed over focused curiosity.

Structural contexts

In retrospect, Lederberg's position in the communication network and his not yet having a career in science seem consequential for his identifying the problem of bacterial sex, for his developing a method for its investigation and for his being in a position to do the research. Tatum was led to the problem independently for somewhat different reasons[27]. Lederberg was unenthusiastic about classical genetics when he arrived at Columbia College in 1941. His interest in "understand[ing] the chemical nature of life" led him to spend much of the next four years studying chemistry, cytology and physiological embryology. But he was not ignorant of classical genetics and the Columbia biologists were well connected with the New York network of scientific communication about genetics. Dobzhansky was a central figure. Arthur Pollister was in close touch with researchers at the Rockefeller Institute. Alfred Mirsky worked at both institutions. Lederberg not only learned quickly about the neo-darwinian developments described earlier but he also heard about the work of Avery *et al* from Mirsky and promptly read their paper. If the Avery *et al* work sharpened Lederberg's interest in bacterial reproduction, Dubos' review of the inconclusiveness of evidence on sexual reproduction sharpened his scepticism, the cognitive and structural elements were coalescing.

In Lederberg's second year at Columbia he met Francis Ryan, an assistant professor, who had just completed a postdoctoral fellowship at Stanford with Beadle and Tatum. It was Ryan who first told him about the work on biochemical genetics and who persuaded him that chemistry and genetics were not as far apart as he had thought[27]. It was also Ryan who generously provided Lederberg with laboratory facilities, catalysed his association with Tatum, and, most importantly, encouraged, educated and socialized him as a scientist. Columbia provided Lederberg with a multifaceted and advantageous structural context for his scientific development and for the initiation of a high-risk, high-stakes research programme.

Lederberg's plan for research was well worked out by July 1945, when he was a second-year student at Columbia Medical School but continued to work in Ryan's laboratory. The research might have been pursued at Columbia, but Ryan and Lederberg both recognized that an association with Tatum would be valuable. In particular, his experience in microbial biochemistry could help broaden Lederberg's education beyond the opportunities available on Morningside Heights. Furthermore, Tatum, then in the process of moving to Yale, was rapidly becoming recognized as a scientific leader. He could provide Lederberg with better access not only to information, research materials and fellowship support, but also to the invisible college of the emerging scientific discipline of biochemical genetics. The impact of such informal ties between investigators on the directions and pace of scientific research has yet to be properly investigated.

Lederberg's status as a medical student was less an obstacle to his investigating bacterial sex than might be supposed. Though much of his time was spent on course work, he was not subject to the constraints that apply in the early years of study for the PhD He did not, like ordinary graduate students, have to choose a research problem that would be suitable for a thesis and publication Being marginal[40] to the biological research enterprise, he could afford to take on a high-risk problem The search for bacterial sex was definitely high-risk, it was not one likely to produce useful and publishable findings After all, not observing bacterial recombination would scarcely demonstrate that it did not exist The risk of a negative finding using *E coli* is now known precisely, bacterial recombination being observed in only five per cent of all strains with the techniques used in 1946

For a different set of reasons, Tatum could also afford research on a high-risk problem at the time He had a variety of projects in process in his laboratory and could manage to take a long-shot experiment that required little time and little money For both men, bacterial recombination was a good gamble, failure would have low marginal costs for each but promised large if prospectively improbable returns High-risk investigations are not equally feasible for all scientists They fall to the comparatively well-established or to those who are marginal as Lederberg was in 1946 Those who solve high-risk problems, having chosen them in the first place, may more often come from the ranks of the well established than from neophytes thus contributing to he accumulation of advantage[41] Risk-taking in science is a matter not only of psychological daring but also of position in the social structure[14,42]

After a brief correspondence, Tatum invited Lederberg to work at Yale He arrived in March 1946, genetic recombination in *E coli* was experimentally observed early in May The results were so arresting that Tatum arranged for Lederberg to present them at the Cold Spring Harbor Symposium to be held in July The publications which followed[3,4,43] did not merely describe the results of the initial laboratory investigation They are the product of critical discussion of those results at that meeting and of follow-up experiments done immediately afterwards[27] The dynamics or organized scepticism in science[44] can be observed in the records of that meeting and later in responses to the papers announcing the discovery Even as first published, discoveries are not simply reports of events intially observed in the laboratory[45,46] but often are also the outcomes of exchange between contributors and their critics Treating scientific contributions as the results of inquiry, criticism and subsequent work makes problematic the custom of designating this or that scientist as the exclusive contributor and focusses attention on the operation of organized scepticism and its effect on shaping the meaning and assessment of those contributions

Conclusions

Was the investigation of sexual recombination in bacteria postmature, that is, conducted significantly later than it could have been? The problem was obscured for decades by the Cohn–Koch dogma of monomorphism and the conviction that bacterial variation resulted only from contamination This was so even for Beijerinck and members of the Delft School who did not subscribe to strict monomorphism, knew how to mark microbial strains by their fermentative and nutritional characteristics (the basis of Lederberg's design), knew about Mendelian segregation in plants, and might have appreciated the significance of sexual recombination in bacteria were it observed But, they were committed to the view that bacteria reproduced only by fission and did not consider the phenomenon problematic In principle, the investigation was technically feasible by 1908, as demonstrated by Browning's[47] use of drug resistance as a selective marker, an early anticipation of the Lederberg–Tatum work But Browning dealt with a different organism, reported a negative result, and used terminology not readily transferable to the case of bacterial recombination In the 1930s, bacterial sex was still viewed as unlikely, even as a disputable idea Yet had it been demonstrated experimentally, it would have been understood and appreciated by geneticists and possibly even by bacteriologists

This case study suggests that problem-identification and selection in science have features deserving further analysis First, the solutions to two classes of problems are apt to be postmature those which do not survive competition for scientists' attention when they first appear because they seem insignificant, unfeasible or both and those which are obscured by prevailing cognitive commitments or have no socially and cognitively defined disciplinary home Second, in calculating the probable returns on selecting problems for investigation, scientists assess the likelihood of error and this contributes to the continuing neglect of certain problems that have a history of being error-prone Third, the feasibility of addressing high-risk problems in science and so of making major advances in this way is not equal for all investigators, they are left largely to the well-established who can afford them and to others who have a smaller stake, for structural reasons, in their immediate record of publication What scientists define as problematic and worthy of investigation are the products of interactions between cognitive and social processes

Helium isotopes in sedimentary basins

E. R. Oxburgh, R. K. O'Nions & R. I. Hill*

Department of Earth Sciences, University of Cambridge, Downing St, Cambridge CB2 3EQ, UK

Measurements of helium isotopes in the ground waters and natural gases of sedimentary basins reveal that some possess a major component of mantle-derived helium, apparently related to their mechanism of formation. Neogene basins formed by loading do not involve introduction of significant mantle helium, whereas those formed by extension do.

MANTLE degassing occurs principally through young oceanic lithosphere, and to a lesser extent through tectonically active portions of continental crust[1-3]. The phenomenon is particularly well documented for mantle-derived helium, which contains more ^{3}He than crustal helium of purely radiogenic derivation. Stable parts of the continents are essentially impermeable to mantle volatiles, and helium from even the deepest boreholes has an isotopic composition characteristic of radiogenic production. But the formation of sedimentary basins involves deformation of the continental lithosphere which, depending on the processes involved, may or may not allow transient transfer of mantle-derived fluids into the crust. Here we suggest that the isotopic composition of helium in the ground waters and natural gases sampled from sedimentary basins may indicate the processes that acted during their formation.

Sedimentary basins may develop in different tectonic settings, and often the mechanisms involved in their formation remain poorly understood. Studies of the rates of basin subsidence, and the spatial and temporal variations of these rates, have shown that some basins have formed largely through thermal subsidence, whereas others appear to result from tectonic loading of the crust. Various explanations have been offered for basin formation through thermal subsidence[4-7]: one involves extension (or boudinage) of the lithosphere and upwelling of asthenosphere within the stretched zone[6], another involves stretching of the lithosphere without thinning, extension being accommodated by the emplacement of mantle-derived dykes[7]. These are not mutually exclusive alternatives, and elements of both could be present in the development of any one basin. The North Sea basin provides a good example of thermal subsidence[8,9], and the demonstration of crustal thinning as well as aspects of the early subsidence history have suggested that this basin developed largely through lithospheric stretching.

When lithospheric stretching is accompanied by passive uprise of the asthenosphere, decompression may produce some melting[10], and mantle volatiles may be released into the crust. When coupled with the elevated temperatures expected in the thinned crust[6], such processes may facilitate the transport of mantle helium to shallow crustal levels. The dyke emplacement model for lithospheric extension[7] could involve the release of mantle-derived volatiles from basaltic melts emplaced into the crust beneath the developing sedimentary basin.

Loading basins form where the crust is depressed adjacent to a tectonically imposed load, such as a stack of thrust sheets. Mantle melting is not expected to accompany the development of such basins, and enhanced transfer of mantle-derived fluids into the crust is not anticipated. The Molasse and East Carpathian basins of the Alpine chain and many of the basins east of the Canadian Rockies are examples of loading basins.

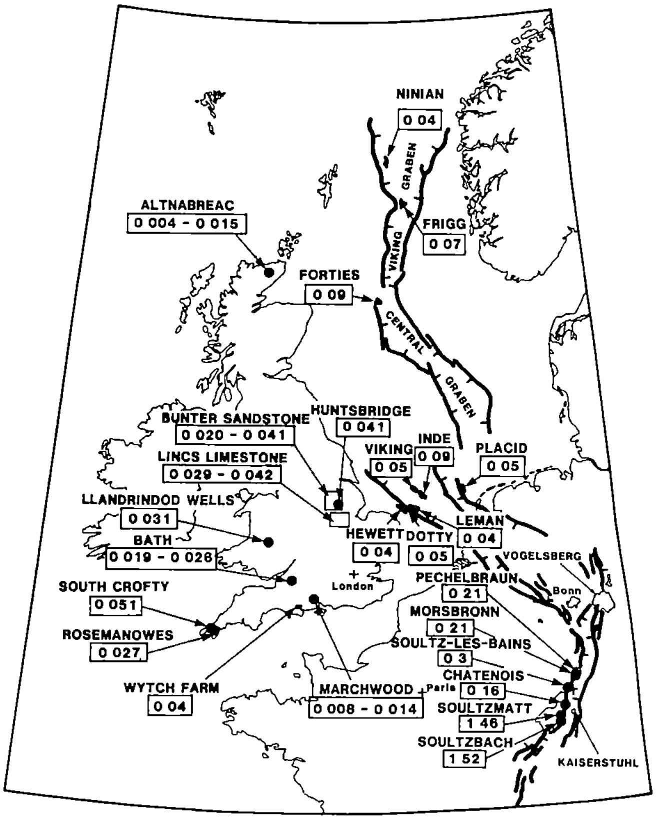

Fig. 1 Isotopic composition of helium in ground waters and natural gases in the mainland United Kingdom, North Sea and Rhinegraben. The values shown are for R/R_a, the ratio of the ^{3}He/^{4}He ratio of the sample (R) to that of the atmosphere (R_a). Natural gas samples from the North Sea basin have R/R_a values close to the expected radiogenic production ratio. A substantial mantle-derived helium component is present in samples from the southern part of the Rhinegraben. Data from ref. 12 and unpublished work.

Helium isotope results for sedimentary basins

Helium isotope data are available for ground-water and natural gas samples from a number of sedimentary basins of contrasting age and style[2,11-13] (Figs 1-3). The Molasse basin north of the Alps, the Pannonian basin of Hungary, the Rhinegraben and the Niigata basin of western Honshu (Japan) are used as examples of young (Neogene) sedimentary basins, the Mesozoic and Palaeogene North Sea basin and the Palaeozoic Hugoton–Panhandle gas fields provide information on older structures. Of these, only the Molasse basin is clearly formed by loading. Samples from the Niigata basin[11], the North Sea[12] and the Hugoton–Panhandle[13] are all from producing gas wells, samples from the Rhinegraben[12] and from the Molasse and Pannonian basins (Fig. 2) were collected from producing water wells, and from deep-source springs. The two sampling modes each provide representative samples of the local crustal helium, in many cases

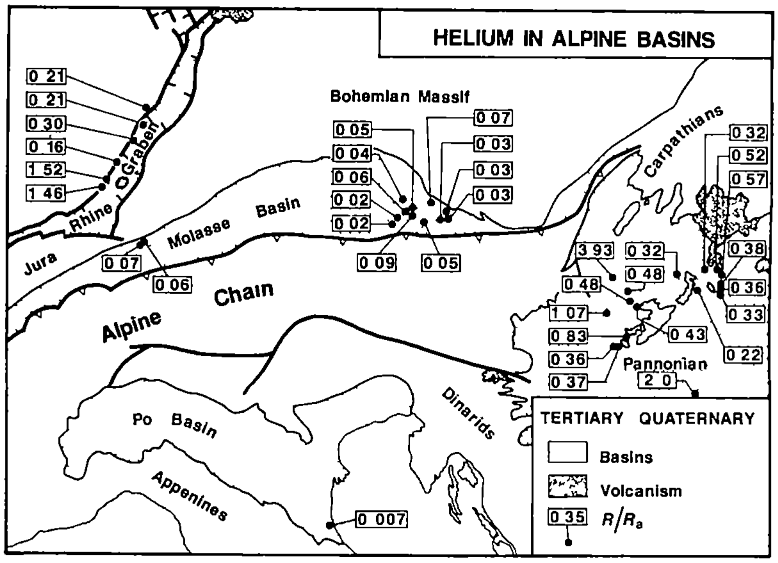

Fig. 2 R/R_a values for ground waters from Neogene basins Values for the Molasse basin (refs 30, 31 and W Balderer, personal communication) show little evidence of the presence of mantle-derived helium In contrast, the Pannonian basin samples[32] all contain a mantle component

it has been demonstrated that natural gases and formation waters from a single basin have comparable ^{3}He/^{4}He ratios[14–16] The ^{3}He/^{4}He ratios (R) for samples from the various basins have been normalized to the atmospheric ^{3}He/^{4}He ratio ($R_a = 1\ 41 \times 10^{-6}$) and are presented in Figs 1 and 2

Figure 3 summarizes the available data, which range from 0 02 R_a to 6 1 R_a Interpretation of the two extremes of the histogram is straightforward values >4 R_a indicate a substantial mantle helium component ($\geq 50\%$), whereas values close to 0 02 R_a indicate such low ^{3}He abundances that no mantle helium component is recognizable The isotopic composition of radiogenic crustal He is controlled essentially by the abundance of lithium ^{4}He is generated by the ^{238,235}U, ^{232}Th decay series, whereas ^{3}He is derived from ^{6}Li by an (n, α) reaction The composition of radiogenic helium may vary locally within a rock, reflecting the distribution of uranium, thorium and lithium between different phases and on different length scales This problem has been examined in some detail[16–19] and it appears that the composition of helium released from rocks is averaged over many possible generation sites As helium samples are representative of relatively large ground-water or natural gas systems, for normal crustal lithologies radiogenic helium R/R_a is expected to average $\leq 0\ 04$, which is about the upper limit for water samples collected from different parts of the stable United Kingdom crust (refs 12, 20 and unpublished data) Although local departures may arise from anomalously lithium-rich lithologies, R/R_a values $>0\ 08$ are interpreted here as being mixtures of radiogenic helium ($R/R_a \approx 0\ 04$) and mantle helium ($6 < R/R_a < 10$) Anthropogenic ^{3}He (derived from bomb tritium) can be present only in very young (post-1950) ground-water components and needs to be considered only in the case of Molasse basin waters The other fluids analysed either have helium contents too high for their composition to have been significantly affected by bomb tritium, or are demonstrably too old to be modified in this way, or both

Neogene basins The Niigata, Molasse and Pannonian basins began to form in the latest Palaeogene or early Neogene The Niigata basin is an epicontiental back-arc basin behind the active northern Honshu volcanic arc Subsidence began at ~23 Myr BP, and a thick sequence of volcanic and volcaniclastic rocks was deposited on a basement of Palaeozoic metamorphic rocks and Cretaceous granites Volcanic input to the basin has waned since the end of the Miocene (6 Myr BP), although clastic sedimentation and deformation have continued to the present day

Unlike the Niigata basin, whose development accompanied the opening of the Japan Sea[21], the Pannonian basin is entirely intra-continental It truncates many of the thrust units of the Alpine belt, and subsidence is associated with extensional and strike-slip faulting, although the broader tectonic setting is not entirely clear[22,23] Volcanism within the Pannonian basin continued until the end of the Pliocene The southern Rhinegraben is a narrow intra-cratonic rift which has been accumulating sediment since the Palaeogene The region is seismically active today[24], and Tertiary volcanism continued until 11 Myr BP The Molasse basin, in contrast, is a classic loading basin formed in the late Palaeogene and Neogene, and is the site of substantial Miocene deposition The basin owes its origin to northward transport of the Upper East Alpine nappes and consequent loading of the Alpine foreland

R/R_a values for helium from the Pannonian basin range from 0 22 to 3 9 and indicate the presence of a mantle-derived component ranging from 2 5 to 50% The values for the Rhinegraben are similar but a little lower, (0 21–1 3)R_a Those from the Niigata basin, however, are in some cases as high as 6 1 R_a, indicating that locally the crust is completely swamped with mantle-derived helium The Molasse basin helium has R/R_a values of 0 02–0 09, and nearly all lie within the anticipated range for radiogenic helium generated within the crust The two highest values ($>0\ 07$) have the largest air corrections and the presence of anthropogenic ^{3}He is suspected, if this explanation of the high values is incorrect, the maximum amount of mantle helium in the Molasse basin samples is 0 9% The Molasse basin shows no evidence for either volcanic activity contemporaneous with basin development nor evidence for crustal thinning For these four young basins, the presence or absence of mantle helium correlates with tectonic setting

Older basins. We now consider two older basins The development of the North Sea basin began with two phases of rifting, in the late Carboniferous (~300 Myr) and Triassic (210–250 Myr), followed by Mesozoic deposition in fault-controlled extensional troughs During the Tertiary and Quaternary there was broad, regional subsidence, with the centre of the basin subsiding more than the margins R/R_a values for helium from major North Sea gas fields and from the adjacent mainland United Kingdom ground waters (Fig 1) range from 0 04 to 0 09 Contamination of these samples by anthropogenic ^{3}He is unlikely Of the three samples with $R/R_a > 0\ 07$, two are from fields adjacent to bounding faults of the Central and Viking grabens These relationships have been discussed in detail by Hooker *et al*[12], who pointed out that the North Sea gas reservoirs are dominated by crustally produced radiogenic helium The weak mantle signature which is locally present could have been acquired either at the time of hydrocarbon migration, or some time later by the leakage of mantle-derived helium upwards along major faults

The Hugoton–Panhandle region of the south-central United

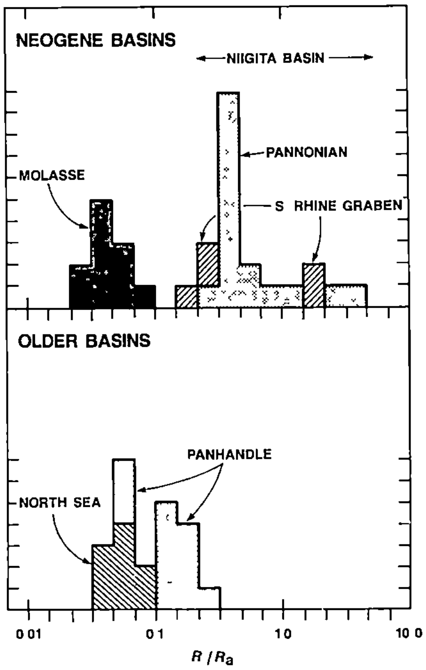

Fig 3 Histograms of helium isotope compositions in Neogene and older sedimentary basins Data sources as for Figs 1 and 2, and from ref 11 for the Niigata basin Note that the plotting intervals on the horizontal axis are unequal because the data are presented on a logarithmic scale

States is of particular interest because it is one of the largest accumulations of natural gas discovered, and has helium contents of up to 2% The gas reservoirs are in rocks of uncertain tectonic setting The southern 'Panhandle' part of the reservoir is draped over a late Precambrian and early Palaeozoic basement high, the Amarillo uplift, and the northern 'Hugoton' fields are situated in sediments of the western margin of the Palaeozoic Anadarko Basin The early history of the region appears to involve an early and rapid subsidence (from 525 to 500 Myr) with little accompanying volcanism, followed by an extended period of sedimentation until ~435 Myr (refs 25, 26)

R/R_a values for Panhandle gases vary from 0 05 to 0 21, and all but one of the thirteen samples analysed by Hill *et al*[13] show a clear mantle-derived component which reaches a maximum of ~2% It is not known when the ^{3}He signature was acquired, and the helium is not necessarily residual from the time of basin formation[13], but could be a recent or contemporary feature associated with igneous activity beneath the northern part of the field

Discussion

Present knowledge of the processes that control the release of mantle volatiles and their ascent through the crust is extremely rudimentary It is clear that igneous activity is very effective in this way, and almost everywhere that measurements have been made on gases issuing from fumaroles, volcanic vents or hot springs associated with volcanic activity, the presence of mantle helium has been detected The three areas described above that have strongest mantle signatures, the Niigata and Pannonian basins and the Rhinegraben, have been the loci of Palaeogene and/or Neogene igneous activity and it could be suggested that degassing of helium from the mantle occurs only in association with melting and therefore with igenous activity We now consider this possiblity further, in the context of sedimentary basin formation

For thermal subsidence models of sedimentary basin formation, the introduction of mantle melts into the crust during the extensional phase is an explicit feature of the dyke injection model and a possible consequence of asthenospheric decompression in stretching models Mantle helium would accompany melts into the crust, and could reach the upper crust before the maturation and migration of hydrocarbons

Of the extensional basins that we have considered, three, the Pannonian basin, the Rhinegraben and the Niigata basin, have been active in the Neogene and are active to varying extents today All have mantle helium in their ground waters, which presumably reflects degassing of helium recently derived from the mantle in each of these areas Ground-water helium is likely to be lost to the atmosphere relatively quickly, and once degassing ends there may be no indication of the former presence of mantle volatiles in these areas, unless samples of crustal fluids are trapped and preserved in some way Torgersen and Clarke[27] have recently argued, from helium concentrations of in ground waters, that degassing of helium from the continental crust is essentially a steady-state process

The North Sea is essentally a Mesozoic basin in which slow subsidence in the axial zone continues today, whereas the Panhandle basin is of Palaeozoic age and has been inactive during the latter part of the Mesozoic and the Tertiary The evidence for mantle volatiles in both cases comes from gases trapped in hydrocarbon reservoirs The question in both cases is when was the mantle gas introduced? If the release of mantle gases associated with basin formation ends before the development of traps, no gases are likely to be preserved The persistence of a mantle helium signature in a sedimentary basin after its formation clearly depends on how long the mantle supply continues, and on the pathways followed by the mantle fluid in the crust At the two extremes will be the gas trapped in the 'tight' reservoir, with the possibility of long retention, and the gas entrained in ground water that makes its way rapidly to the surface to be lost to the atmosphere The decay times associated with these two extremes could range from several hundreds to less than tens of millions of years In the former case the signature will also weaken with time through dilution with locally produced radiogenic crustal helium

In the North Sea, hydrocarbon migration seems in some cases to have occurred nearly 150 Myr after the main extensional phase of basin development If the extensional phase was accompanied by emplacement of mantle-derived melts, then the general absence of mantle ^{3}He in the basin today would require that helium be effectively lost in $\leqslant$100 Myr The presence of mantle ^{3}He in the much older Hugoton–Panhandle rocks must imply either long-term retention from the Palaeozoic and therefore a quite different effective diffusivity structure for the crust compared with that of the North Sea, or alternatively a more recent input of mantle-derived gas

In the case of the North Sea we note that, away from the Central Graben, all well gases analysed from the basin, and all groundwaters from its landward extension, show only radiogenic crustal helium The only sign of mantle helium is a weak signature found along the distant northward extension of the active Rhinegraben faulting system into the North Sea, and it is tempting to suppose that there was a small amount of a localized mantle gas leakage at its northern end

It is not clear whether the ^{3}He-rich helium is derived from the asthenosphere or the lithosphere The convecting upper mantle, as sampled at spreading-ridge axes, is a well-mixed reservoir for helium with $6 < R/R_a < 10$, but the continental lithospheric mantle is also known to contain helium Xenoliths of continental lithospheric mantle material, brought to the surface by recent volcanic activity, contain helium with a range of R/R_a values similar to those characterizing mid-ocean-ridge basalts (MORB)[28], however, it is not known whether helium of such a composition is to be found everywhere in continental lithospheric mantle Helium in fluids from a wide range of circum-Pacific volcanoes has a relatively restricted compositional range around $R/R_a = 6$, and is interpreted as being a mixture of MORB-type helium from mantle beneath the volcanic arc and radiogenic helium derived from the subducted crust[29]

In the absence of evidence to the contrary, we assume that mantle helium is transported into the crust in melts, from which it subsequently degasses, and that melting occurs principally in the hotter asthenospheric material which undergoes decompression beneath at least some sedimentary basins formed by thermal subsidence Note, however, that non-magmatic fluids of mantle origin could satisfy the helium observations equally well

In summary, it appears that the presence or absence of mantle-derived ^{3}He at shallow levels in Neogene sedimentary basins relates to their mechanism of formation The presence of significant amounts of mantle helium in the Pannonian and Niigata basins and the Rhinegraben is related to the introduction and degassing of mantle-derived fluids produced as an integral part of the extensional process Extension by dyke injection cannot be easily distinguished from extension by thinning, although some resolution may ultimately be possible because of predicted differences in the amounts of melt introduced The Molasse basin, a classic loading basin, has developed without the introduction of identified mantle-derived melts or helium The interpretation of the helium isotope composition in sedimentary basins whose development began in the Palaeozoic or Mesozoic, such as the Hugoton-Panhandle and North Sea basins, is less straightforward and requires some knowledge of the time required for the loss of helium in crustal regions undergoing basin development Both of these basins have probably received late additions of mantle volatiles Parts of this work were carried out under a research contract with the European Community, no EN3G 004 UK(H) The ideas presented in this paper have been discussed with many colleagues, for whose comments we are extremely grateful

The c-*erb-A* protein is a high-affinity receptor for thyroid hormone

Jan Sap[*], Alberto Muñoz[*], Klaus Damm[*], Yves Goldberg[†], Jacques Ghysdael[†], Achim Leutz[*‡], Hartmut Beug[*] & Björn Vennström[*]

[†] INSERM, Pasteur Institute, 15 Rue Guerin, 59019 Lille Cedex, France

*Hormone binding and localization of the c-*erb-A *protein suggest that it is a receptor for thyroid hormone, a nuclear protein that binds to DNA and activates transcription In contrast, the product of the viral oncogene v-*erb-A *is defective in binding the hormone but is still located in the nucleus*

THE avian v-*erb-A* oncogene does not by itself cause tumours in animals, but enhances the erythroblast-transforming potential of primary oncogenes, such as v-*erb-B* or other sarcoma-inducing oncogenes[1,2] Two specific effects of v-*erb-A* have been characterized First, erythroblasts transformed by the primary oncogene alone spontaneously differentiate into erythrocytes, and v-*erb-A* completely inhibits this maturation Second, v-*erb-A* allows transformed erythroblasts to propagate in media with wide ranges in *p*H and salt concentration[1-3] These observations suggest that v-*erb-A* in erythroid cells affects ion transport systems and regulatory factors of differentiation[3]

It was recently demonstrated that the v-*erb-A*-specific part of the $p75^{gag\text{-}v\text{-}erb\text{-}A}$ protein (encoded by the avian erythroblastosis virus, AEV-ES4) bears homology to receptors for steroid hormones[4-7], suggesting that the effects of v-*erb-A* could be due to direct transcriptional deregulation of genes responsible for the aforementioned effects[3] To understand these processes better we have isolated and characterized complementary DNA clones of the cellular *erb-A* gene as well as their proteins, and demonstrate that the c-*erb-A* protein has biochemical properties very similar to those of the receptor for the thyroid hormones triiodothyronine (T_3) and thyroxine (T_4) (see ref 8 for review)

Cloning and sequencing of cDNAs for c-*erb-A*

The avian c-*erb-A* gene is transcribed into two messenger RNAs, 4 5 and 3 kilobases (kb) long, that are present at low levels (5-10 copies per cell) in many adult and embryonic tissues (ref 9 and B V, unpublished data) We therefore screened with a v-*erb-A* probe a chicken embryonic cDNA library prepared in λ bacteriophage gt11 (refs 10, 11) Ten positive clones were isolated from the 10^6 plaques screened, and two (clones F1 and U1), that hybridized to probes representing 5′ and 3′ domains in v-*erb-A*, were subjected to nucleotide sequence analysis Figure 1 shows the presence of a long open reading frame of 1,224 nucleotides homologous to v-*erb-A*, suggesting a relative

Fig 1 Nucleotide and predicted amino-acid sequence of the c-*erb-A* cDNA clone F1, and comparison with v-*erb-A* Only those nucleotides and amino acids in v-*erb-A* that differ from c-*erb-A* are shown, whereas deletions are indicated with bars The three short open reading frames in the 5′ untranslated region are shown in bold The *gag* sequence homologous to c-*erb-A* and which bridges the *gag*–v-*erb-A* junction is boxed, nucleotide differences in this sequence are shown in bold letters and deletions with bars The region homologous to the DNA-binding domain of steroid receptors is indicated by arrows The U1 cDNA clone starts at nucleotide −84

Methods Polyadenylated RNA was isolated from a pool of 10-day-old chicken embryos[9], and a cDNA library was constructed in λ gt11 essentially as described[10 11] The library (~10^6 plaques) was screened with a nick-translated 2 5-kb *Pvu*II fragment encoding the viral *erb-A* and *erb-B* sequences from AEV Ten c-*erb-A* positive clones were identified, which were further characterized by hybridization with probes specific for the 5′ and 3′ parts of v-*erb-A*. The inserts of two clones (F1 and U1) hybridizing to these probes were subsequently subcloned into the pTZ vectors[14] for nucleotide sequence analysis using the dideoxy method[50] The F1 clone (1 55 kb) was sequenced in its entirety on both strands, whereas the U1 (2 1 kb) clone was subjected to partial analysis No differences between the clones were detected in the coding or 5′ non-coding sequences

molecular mass ~46,000 (M_r 46K) for the c-*erb-A* protein The coding sequence is preceded by a 5′ untranslated region of at least 288 nucleotides, which contains three short open reading frames (shown in bold letters) 5′ to the long open reading frame In addition, a fourth reading frame, lacking an AUG codon, is open for 413 nucleotides (position −287 to 126) Further analyses are required to determine if this reading frame is used for translation by any of the c-*erb-A* mRNAs Interestingly, the 5′ untranslated sequence is very G+C rich, and a computer-assisted analysis suggested that it could form stable secondary structures (data not shown) Several of the cDNA clones isolated contained long (1–2 kb) sequences downstream of the open reading frame, their nucleotide sequences were not investigated in detail as a preliminary analysis revealed no long open reading frames, thus indicating that they represented 3′ untranslated sequences These sequences were also heterogeneous in length, suggesting that most of the cDNA clones were generated by non-specific and internal priming of the first strand cDNA synthesis

A comparison of the coding sequences of the cellular and viral[3,12] *erb-A* genes revealed that v-*erb-A* has undergone 17 point mutations, of which two led to amino-acid substitutions located in the putative DNA-binding domain and 11 in other regions (Fig 1) Furthermore, the v-*erb-A* protein has lost nine amino acids (nucleotides 1,188–1,215) located three amino acids before the carboxy-terminus Finally, a comparison between the c-*erb-A* coding sequence and the *gag* sequences of Rous sarcoma virus[13] or AEV (ref 3) demonstrated a region with 18/22 and 19/22 nucleotide homology, respectively (boxed in Fig 1), which bridges the junction between the *gag* and v-*erb-A* domains in $p75^{gag\text{-}v\text{-}erb\text{-}A}$ As a consequence, the amino-terminus of the c-*erb-A* polypeptide is 12 amino acids longer than the *erb-A*-specific part of $p75^{gag\text{-}v\text{-}erb\text{-}A}$, when taking into account the region homologous to *gag* This also suggests that c-*erb-A* was fused to *gag* either by homologous recombination at the DNA level or during retrotranscription of c-*erb-A* mRNA packaged into virions

Characterization of the c-*erb-A* protein

To determine whether the cDNA clones encode an authentic c-*erb-A* protein, one of them (clone F1) was cloned into the polylinker region of the pTZ19 plasmid vector[14] to allow *in vitro*

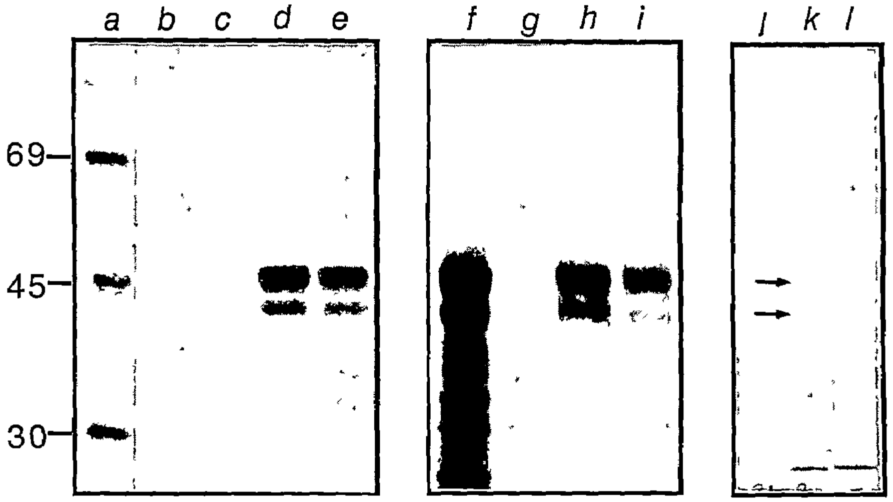

Fig. 2 Synthesis and immunoprecipitation of the c-*erb-A* protein. Capped mRNA, synthesized *in vitro* using T7 RNA polymerase, was translated in rabbit reticulocyte lysates. Lane *a*, marker proteins (sizes shown being relative molecular masses in thousands), lane *b*, unprogrammed lysate, lane *c*, translation with RNA from clone F1 containing the 288-nucleotides long 5′ untranslated sequence, lanes *d* and *e*, RNA from clones F1 and U1 with only 38 nucleotides of 5′ untranslated sequence remaining. Aliquots of the translation products were immunoprecipitated with two different anti-erb-A antisera. Total translation products with 5′-truncated RNA (lane *f*) were immunoprecipitated with preimmune serum (lane g) and with two different anti-erb-A antisera (lanes *h* and *i*). Chicken embryo fibroblasts, transiently transfected with expression plasmids, were labelled with [^{35}S]-methionine for 2 h. Immunoprecipitations using preimmune or anti-erb-A antiserum with lysates from cells receiving a c-*erb-A* expression plasmid are shown in lanes *i* and *k*, respectively. Immunoprecipitation with anti-erb-A antiserum of lysates from cells transfected with the plasmid lacking insert is shown in lane *l*.

Methods To reduce the length of the untranslated leader sequence, plasmids containing the entire F1 and U1 cDNA clones in the appropriate orientation in the *Eco*RI site of pTZ 19 were cleaved with *Eag*I 38 nucleotides upstream of the translation initiation codon, and with *Sma*I in the polylinker region of the vector, treated with the Klenow fragment of DNA polymerase I in the presence of all four deoxynucleotide triphosphates, and religated at low DNA concentration. For *in vitro* transcription, plasmids were linearized with *Hin*dIII or *Eco*RI, treated with proteinase K, extracted with phenol-chloroform and precipitated. Transcription was done with T7 DNA polymerase (100 units ml^{-1}, Biolabs) at 37 °C in 40 mM Tris *p*H 7.9, 6 mM $MgCl_2$, 2 mM spermidine, 10 mM dithiothreitol (DTT), 0.5 mM of the four ribonucleotide triphosphates, 0.5 mM ^{7}mGpppG (Boehringer), 0.1 mg ml^{-1} bovine serum albumin (BSA), 1,000 U ml^{-1} Rnasin, at a DNA concentration of 0.1 mg ml^{-1}. Transcripts were translated in micrococcal-nuclease-treated rabbit reticulocyte lysates (NEN) in the presence of 3 mCi ml^{-1} [^{35}S]-methionine under conditions suggested by the manufacturer. Lysates were diluted 100-fold with lysis buffer before immunoprecipitation, kept on ice for 30 min and cleared by centrifugation at 15,000 r.p.m. for 30 min. Precipitations were essentially as described[3,51] using 5 μl of 1:10 diluted antiserum. Proteins were separated by SDS-polyacylamide gel electrophoresis on 10% gels, and the gels fluorographed and exposed at −70 °C. The anti-erb-A antisera were directed against the 5′ and 3′ domains of v-*erb-A* expressed in bacteria, and will be described in detail in a separate paper. To express c-*erb-A in vivo*, the 5′-truncated F1 clone was cloned into the expression plasmid pSV2 (ref. 15).

transcription with the T7 RNA polymerase and subsequent translation in reticulocyte lysates. In addition, to test if the 5′ untranslated sequence influenced the efficiency of translation, two constructs were made with cDNA from the clones F1 and U1, each lacking 250 nucleotides of this sequence. Figure 2 shows that RNA lacking the 5′ sequence (lanes *d* and *e*) directed the synthesis of a major 46K protein, whereas translation with RNA still containing this sequence gave only minor incorporation (lane *c*). Furthermore, the 46K protein as well as a minor 40K polypeptide were identified as c-*erb-A* proteins by immunoprecipitation with monospecific anti-v-erb-A antisera recognizing N- or C-terminal epitopes, respectively (Fig. 2, lanes *h* and *i*).

To demonstrate that the cDNAs directed the synthesis of c-*erb-A* protein also *in vivo*, chicken embryo fibroblasts were transiently transfected with a plasmid expressing c-*erb-A* from the simian virus 40 (SV40) promoter[15]. The cells were labelled after 48 h with [^{35}S]-methionine, lysed and subjected to immunoprecipitation with anti-erb-A antiserum. Figure 2 (lane *k*) shows that the c-*erb-A*-transfected cells contained 46 and 40K proteins, whereas no protein was specifically precipitated from cells transfected with the vector lacking an insert (lane *l*). The anti-erb-A antiserum also reacts with a 46K and a 40K protein expressed at very low levels in many types of avian cells (J.G., in preparation), suggesting that the polypeptides expressed from the cDNA represent authentic c-*erb-A* proteins.

The c-*erb-A* protein binds thyroid hormone

To identify a ligand for the c-*erb-A* protein we first searched the literature for a nuclear hormone receptor expressed in many types of cells that had M_r ~46K. The criteria were fulfilled by the nuclear receptor for the thyroid hormone triiodothyronine (T_3), as a 47K polypeptide that binds T_3 is expressed in many tissues[8,16,17]. Accordingly, c-*erb-A* protein produced by *in vitro* translation in reticulocyte lysates was incubated with [^{125}I]-labelled T_3 in the presence or absence of a 1,000-fold excess of unlabelled hormone, and tested for binding of hormone with a filter binding assay[18]. Figure 3*A* shows that lysates programmed with c-*erb-A* RNA containing the short 5′ untranslated sequence bound the radiolabelled hormone (column *a*, open), and that unlabelled T_3 (column *b*, open) or D-T_4, an analogue of T_3 which is biologically inactive but binds to the T_3 receptor[19], (column *c*, open) complete with most of this binding. In contrast, the binding exhibited by mock-programmed lysates in the presence or absence of competitor (stippled columns *a*, *b* and *c*) was similar to that determined for the c-*erb-A* lysate competed with unlabelled T_3, suggesting that the c-*erb-A* protein specifically binds T_3. Similar results (data not shown) were obtained when the binding was tested by chromatography on Sephadex G75 columns[20]. In addition, a 1,000-fold molar excess of unlabelled dexamethasone, oestradiol, progesterone, aldosterone, testosterone, vitamin D_3 (7-dehydrocholesterol), or tyrosine did not compete with radiolabelled T_3 for binding to c-*erb-A* containing lysates (open bars, Fig. 3*A*). Finally, an excess of these compounds did not compete with [^{125}I]-T_3 for nonspecific binding to mock-programmed lysates (compare the stippled columns *d*–*j* to *a*).

To demonstrate directly that the observed binding was due to c-*erb-A*, lysates containing *in vitro* translated c-*erb-A* protein were subjected to immunoadsorption with anti-erb-A or anti-erb-B antisera bound to protein A-Sepharose beads. The depleted samples were then assayed for binding of [^{125}I]-T_3 in the presence or absence of competitor. Column *m* in Fig. 3*A* shows that the adsorption with anti-erb-A antibodies removed about 70% of the specific binding activity, whereas extracts adsorbed with preimmune or anti-erb-B antisera exhibited no decreased

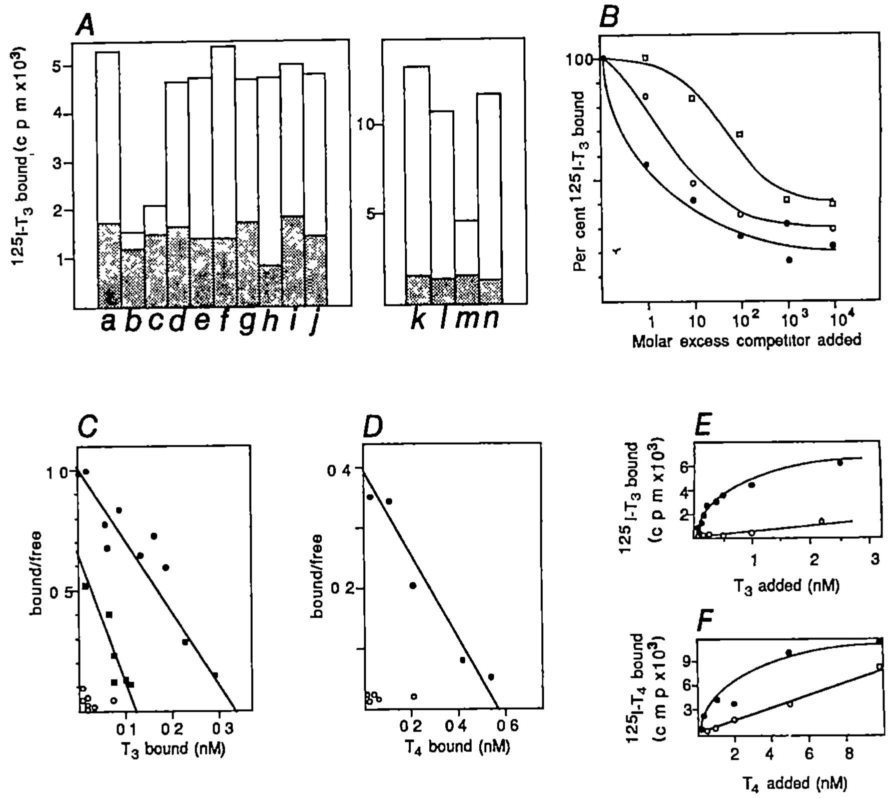

Fig 3 Ligand-binding properties of the c-*erb-A* protein produced by *in vitro* translation *A*, left, Reticulocyte lysates programmed with plus strand (open bars) or minus strand c-*erb-A* RNA (stippled bars) were incubated with 1 nM [^{125}I]-T$_3$ in the presence or absence of 1 μM of various unlabelled competitors *a*, no competitor, *b*, T$_3$, *c*, D-T$_4$, *d*, dexamethasone, *e*, oestradiol, *f*, progesterone, *g*, aldosterone, *h*, testosterone, *i*, vitamin D$_3$, *j*, tyrosine right, open bars show that the binding activity of c-*erb-A* protein for [^{125}I]-T$_3$ was reduced in lysates treated with anti-erb-A but not with anti-erb-B or preimmune sera Antisera *k*, no antibodies, *l*, pre-immune serum, *m*, anti-erb-A, *n*, anti-erb-B Stippled bars show binding in the presence of a 1,000-fold excess of unlabelled T$_3$ *B*, Competition binding with analogues of T$_3$ Lysates containing c-*erb-A* were incubated with 1 nM [^{125}I]-T$_3$ in the presence of the indicated molar excesses of unlabelled competitor Reverse T$_3$ (rT$_3$) is 3,3′,5′-thyronine ●, T$_3$, ○, T$_4$, □, rT$_3$ *C*, Scatchard analysis of T$_3$ binding Lysate extracts were diluted (●) 7-fold (K_d = 0 33 mM) or (■) 20-fold (K_d = 0 21 nM), ○, extract of mock-programmed lysate *D*, Scatchard analysis of T$_4$ binding ●, 7-fold diluted extract (K_d = 1 4 nM), ○, extract of mock-programmed lysate *e*, *f*, Saturation analysis of T$_3$ and T$_4$ binding Binding measured in extracts of (●) c-*erb-A* protein-containing or (○) mock-programmed lysates Nonspecific binding was determined by parallel incubations with 1 μM unlabelled T$_3$ or T$_4$

Methods All assays were done with protein synthesized *in vitro* essentially as described in Fig 2, except that DNA was purified on small Sepharose CL6B columns before transcription, no label was included in the translation reactions, and translation lysates were obtained from Amersham Aliquots of the lysate were incubated overnight at 0-4 °C with L-[3′-^{125}I]-triiodothyronine (3,000 mCi mg^{-1}) or L-[3′,5′-^{125}I]-thyroxine (1,500 mCi mg^{-1}, both Amersham) at the indicated concentrations (generally 0 5-2 0 μl lysate in a total volume of 10 μl) in binding buffer (50 mM NaCl, 2 mM EDTA, 5 mM mercaptoethanol, 20 mM Tris *p*H 7 5, 10% glycerol) Radiolabelled hormone was dried under vacuum to remove ethanol when the final isotope concentration used would exceed 2 nM Bound radiolabelled hormone was determined[18] by filtration at 4 °C using Millipore HAWP 02500 filters prewetted with 3 5 ml binding buffer Filters were washed by suction with 5 ml binding buffer at 4 °C three times, and were counted in a gamma counter Control lysates were programmed with RNA transcribed from a clone with the c-*erb-A* cDNA in the opposite orientation For immunodepletion, 5 μl of programmed lysate was diluted fivefold with binding buffer, incubated with 2 μl undiluted antiserum for 4 h at 4 °C, and adsorbed for 30 min to protein-A-Sepharose (saturated with erythroblast extract and washed extensively with binding buffer)

binding (columns *l* and *n*) Finally, the proteins adsorbed to the anti-erb-A antibodies bound no T$_3$, presumably due to conformational changes or steric hindrance imposed by the antibodies (data not shown)

The receptors for thyroid hormone bind with lower affinity analogues[21,22] of T$_3$, such as thyroxine (T$_4$) and reverse T$_3$ (rT$_3$) We therefore tested if higher concentrations of these analogues would be required to compete with labelled T$_3$ for binding to c-*erb-A* protein Figure 3*B* shows that T$_4$ was 5-10-fold and rT$_3$ was 50-100-fold less efficient than unlabelled T$_3$ in competing with [^{125}I]-T$_3$ These relative efficiencies are similar to those reported for competition of [^{125}I]-T$_3$ binding to the thyroid hormone receptors[21,22] and reflect the different biological activities of these products

To determine accurately the affinity of c-*erb-A* protein for thyroid hormone, we performed Scatchard analyses[23] with labelled T$_3$ and T$_4$ Because these hormones have been reported to bind with low affinity to unspecific sites at high protein concentrations[24] which affect the dissociation constants measured, we determined the K_d of c-erb-A for T$_3$ using reticulocyte lysates diluted to different concentrations Figure 3*C* (filled symbols) shows that the K_d for T$_3$ was between 0 21 and 0 33 nM with 20- and 7-fold diluted extracts, respectively, whereas the K_d for T$_4$, determined in a separate experiment with a 7-fold diluted extract, was 1 4 nM (Fig 3*D*) In contrast, Scatchard analyses done with mock-programmed lysates only indicated the presence of low-affinity/high-capacity binding sites (open symbols) The affinities of the c-*erb-A* protein for T$_3$ and T$_4$ are similar to the published values obtained with the thyroid hormone receptor in whole cells and in crude nuclear extracts[22,25]

Finally, the results from the saturation binding experiments (Fig 3*E* and *F*) showed that the high-affinity sites (closed symbols) were saturable with low concentrations of hormone, whereas the low-affinity sites present in the mock-programmed lysates were non-saturable (open symbols) By calculating the amount of [^{35}S]-methionine-labelled c-*erb-A* protein in the lysates and comparing to the amount of T$_3$ bound, we estimate that 5-10% of the total *in vitro* synthesized protein bound radiolabelled hormone, a result similar to those found for *in vitro* synthesized steroid receptors[26]

Cellular but not viral *erb-A* protein binds T$_3$

The T$_3$ receptor is nuclear regardless of whether or not it has bound hormone[8] To verify that the c-*erb-A* protein binds T$_3$ also *in vivo*, and to test the hormone binding capacity of p75$^{gag\text{-}v\text{-}erb\text{-}A}$, chicken embryo fibroblasts containing c-*erb-A* or v-*erb-A* were tested for hormone binding The c-*erb-A* gene was expressed from a replication-competent retrovirus vector[27], whereas a *wt* and an inactive v-*erb-A* gene (v-*erb-A2*$^-$, ref 1) were expressed from retrovirus constructs also conferring resistance to the drug G418 To measure nuclear T$_3$ binding *in vivo*, transfected and fully infected cell cultures were incubated with [^{125}I]-T$_3$ for three hours, and the radioactivity in the isolated nuclei determined Figure 4 (left) shows that the nuclei (open

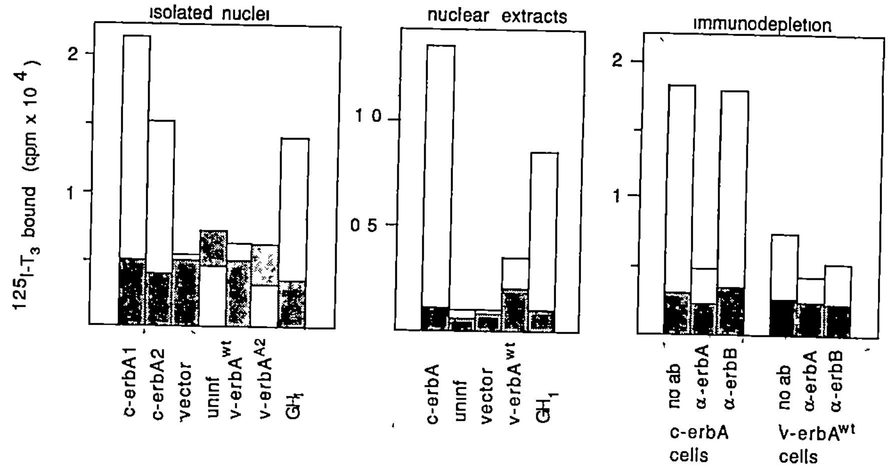

Fig 4 Hormone-binding properties of c-*erb-A* and v-*erb-A* proteins produced *in vivo* Left panel, Cells expressing c- or v-*erb-A* were incubated for 3 h with [^{125}I]-T$_3$, and the radioactivity in the nuclei determined Middle, Hormone binding by nuclear extracts incubated with [^{125}I]-T$_3$ *in vitro* Right panel, Reduction of *in vitro* binding activity in nuclear extracts by adsorption with anti-erb-A antisera Open bars show binding of radiolabelled hormone in the absence of competitor, whereas stippled bars indicate binding of [^{125}I]-T$_3$ in the presence of a 1,000-fold excess of unlabelled hormone

Methods The F1 cDNA clone containing only the short 5′ leader sequence was cloned into a modification of the replication competent avian retrovirus vector 779/989, a derivative of a previously described vector[27] Virus constructs expressing *wt* or mutant (v-*erb-A2*$^-$, ref 1) v-*erb-A* genes were constructed by excising the v-*erb-B* gene from AEV with *Apa*I and *Eco*RI, followed by appropriate modification and insertion of the *Bgl*III–*Bam*HI fragment of the Tn*5 neo*^{R} element The constructs were introduced into chicken embryo fibroblast cells by the $Ca_3(PO_4)_2$ precipitation technique[52 53] In the case of the c-*erb-A* construct, virus infection was monitored by reverse transcriptase activity in the culture media, whereas cells containing the v-*erb-A-neo*^{R} viruses were superinfected with RAV1 helper virus and then isolated after selection for G418 resistance Control experiments showed that these viruses expressed v-*erb-A* at levels similar to those found in AEV-transformed cells (not shown) Cells were grown in Eagle's medium plus 5% fetal calf serum and 2% heat-inactivated chicken serum For analysis of nuclear T$_3$-receptor content, cells grown for 24–48 h in media containing T$_3$-depleted[54] serum were trypsinized, washed twice with Hank's and resuspended at ~3×10^6 cells ml^{-1} in T$_3$-free medium supplemented with 0 15 nM [^{125}I]-T$_3$ for 3 h Cells were subsequently washed with Hank's, and lysed in 1 ml 50 mM Tris *p*H 7 85, 1 1 mM $MgCl_2$, 0 5% Triton-X-100 at 0 °C Nuclei were collected by centrifugation (1,500 r p m for 5 min) and were washed once more in lysis buffer before counting GH$_1$ cells were cultured in Eagle's medium containing 10% horse serum and 2 5% fetal calf serum Isolation of nuclei and preparation of nuclear extracts were done employing techniques used for isolation of nuclear T$_3$ receptor[55], except that inhibitors of proteolysis were included in all steps of isolation Experiments on [^{125}I]-T$_3$ binding with nuclear extracts and immunodepletion were done as described in Fig 3

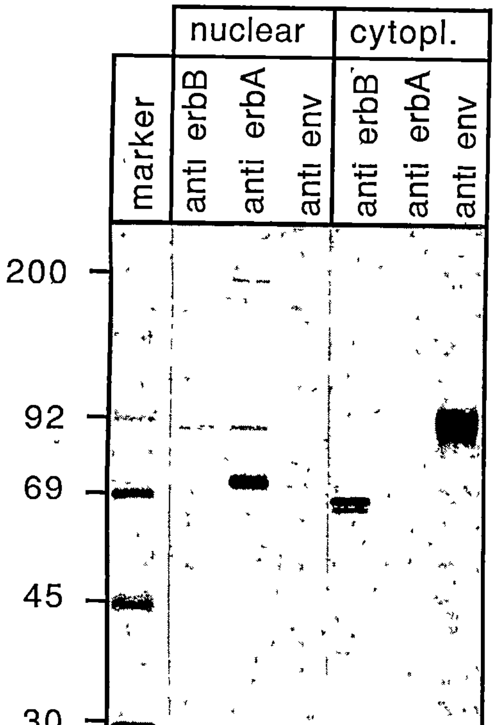

Fig 5 Demonstration of a nuclear localization for the v-*erb-A* protein Cell fractionation experiments with AEV-transformed erythroblasts were done as described in Fig 4 Labelling of cells and immunoprecipitations were carried out as described in Fig 2 Sizes for markers are relative molecular masses in thousands

columns) from two different cultures of c-*erb-A* expressing cells (c-*erb-A*1 and 2) bound [^{125}I]-T$_3$ at levels similar to that found in the nuclei of GH$_1$ cells, a rat pituitary line expressing 1–2×10^4 T$_3$ receptors per cell[28,29] In addition, a 1,000-fold excess of unlabelled T$_3$ competed with this binding (stippled columns) In contrast, only a low amount of specific T$_3$ binding was found in the nuclei from the *wt* and the mutant v-*erb-A* expressing cells, or the cells infected with the replication competent vector lacking c-*erb-A* insert Similar results were obtained when nuclear extracts, prepared from unlabelled cells, were tested for binding of [^{125}I]-T$_3$ *in vitro* (middle panel) Again, receptors from the c-*erb-A* and the control GH$_1$ cells bound radioactivity at levels 8–12-fold higher (open bars) than that observed when binding was done in the presence of an excess of unlabelled T$_3$ (stippled bars) In contrast, the binding seen with extracts from uninfected cells or cells expressing v-*erb-A* was only 1 3–1 7 times background Lastly, adsorption with anti-erb-A antisera of nuclear extracts from c-*erb-A* but not v-*erb-A* cells reduced the specific binding by 77% (Fig 4, right panel), demonstrating that the high T$_3$ binding was dependent on c-*erb-A* protein

To exclude the possibility that lack of nuclear hormone binding by v-*erb-A*-expressing cells was due to cytoplasmic localization of p75$^{gag\text{-}v\text{-}erb\text{-}A}$, a cell fractionation experiment was done Erythroblasts transformed by AEV were labelled with [^{35}S]-methionine, and nuclear and cytoplasmic extracts, prepared using techniques described for the isolation of the T$_3$ receptor[17], were immunoprecipitated with antisera against v-erb-A, v-erb-B and the viral envelope glycoprotein Figure 5 shows that the v-*erb-A* protein was present predominantly in the nuclear extract, whereas the v-*erb-B* and *env* proteins partitioned in the cytoplasmic fraction Previous reports have suggested that v-*erb-A* is localized in the cytosol[30], these cell fractionation experiments were however done under conditions that may not preserve the nuclear localization of at least the unoccupied oestradiol receptor[31,32]

Discussion

Several lines of evidence suggest that the avian c-*erb-A* gene codes for a thyroid hormone receptor the molecular weight of the c-*erb-A* protein is the same as that of a previously characterized receptor, it binds T$_3$ and its analogues with affinities typical of the T$_3$ receptor, binding activity can be removed with anti-erb-A antibodies, and both the thyroid hormone receptor and c-erb-A are expressed at low levels in many tissues Finally, Weinberger and collaborators have demonstrated that a human c-*erb-A* protein also binds thyroid hormone *in vitro*[33] However, the evidence is so far based solely on hormone-binding experiments, and definite proof will require the demonstration that the c-*erb-A* protein exerts the same effects *in vivo* as the thyroid hormone receptor

Thyroid hormone induces a wide variety of metabolic effects, for instance increased lipogenesis and ketogenesis These effects have been studied in great detail in liver cells but have also been observed in many other types of tissues[8] The hormone also plays key roles in differentiation, such as the rapid development of frogs from thyrectomized tadpoles, the induction of growth hormone production in the pituitary, and the development of the brain in neonatals by promoting dendrite formation and myelination[8] Interestingly, T$_3$ does not induce the same physiological effects in the brain as in other tissues[34], suggesting that the brain receptor could be distinct from the receptor(s) found in other cells In fact, several c-*erb-A* related genes appear to exist in the human genome A c-*erb-A* gene highly homologous to the avian gene reported in this paper is located on human chromosome 17 (refs 35-38), whereas other distinct genes have been found on chromosome 3 (ref 33)

The thyroid hormone receptor also has a nuclear localization in the unoccupied state as well, and is thought to act by binding to DNA (refs 39, 40) thus inducing or suppressing gene expression in a manner similar to that of steroid receptors[41] The v-*erb-A* protein binds no hormone, yet it is nuclear, binds to DNA *in vitro* (H B and U Gehring, unpublished data) and exerts specific physiological effects in erythroblasts[3] It is therefore likely that p75$^{gag\text{-}v\text{-}erb\text{-}A}$ has lost its hormone-binding capacity as a result of one or several of the mutations it has accumulated Moreover, it is unclear whether it affects the expression of the same genes and in the same manner as the normal receptor, as its presumed DNA-binding region has two amino-acid substitutions It is possible that p75$^{gag\text{-}v\text{-}erb\text{-}A}$, although unable to bind ligand, acts in a similar fashion as the increased nuclear transfer (nt^{i}) mutants previously described for the glucocorticoid receptor[41]

The maturation of erythroid cells is accompanied by synthesis of several components important for proper red cell differentiation, such as band 3, the major anion transporter which also serves as an anchor for erythrocyte cytoskeletal proteins, and hemin, a possible regulatory factor of differentiation[42,43] Interestingly, thyroid hormone regulates the induction of key liver enzymes involved in hemin synthesis[44], and induces increased levels of the Na$^+$/K$^+$ ATPase[45,46] We are therefore currently investigating the possibility that v-erb-A exerts its effects in erythroblasts by suppressing or inducing the synthesis of ion transporters and hemin

It has previously been demonstrated that thyroid status has a modulating effect on neoplasia Administration of thyroid hormone to thyrectomized rodents is a prerequisite for the induction of hepatomas by certain chemicals, indicating a role in the initiating action of the carcinogen In contrast, thyroid hormone appears to promote the growth and metastatic potential of other types of neoplasias, demonstrating an enhancement of tumour progression[47] In addition, the transformation of cultured cells by radiation or adenovirus infection is facilitated by thyroid hormone[48] The v-*erb-A* oncogene of AEV enhances the transforming activity of other oncogenes in erythroblasts but also in fibroblasts (refs 1-3, and M Jansson and B V, unpublished data) In addition, the integration of a hepatitis B viral genome close to a human *erb-A* related gene was recently reported[49] The demonstration that the c-*erb-A* protein has properties similar to those of the T$_3$ receptor may thus represent the first identification of an oncogene that enhances oncogenesis without being able to induce detectable neoplastic effects on its own

We thank Dr Kristina Nordstrom for valuable help and Dr Thomas Graf for helpful suggestions We thank Dr Steve Hughes for providing the replication competent retrovirus vector, and Dr Kåre Gautvik for the gift of GH$_1$ cells A M was supported by a fellowship from the Juan March Foundation during sabbatical leave from Consejo Superior de Investigationes Cientificas, Spain

*The cDNA sequence of human c-*erb-A*, the cellular counterpart of the viral oncogene v-*erb-A*, indicates that the protein encoded by the gene is related to the steroid hormone receptors Binding studies with the protein show it to be a receptor for thyroid hormones*

THE interaction of DNA-binding proteins with specific DNA sequences is one mechanism by which gene transcription is controlled Characterization of the regulatory proteins, which include steroid hormone receptors, should help our understanding of DNA–protein interactions and of the control of gene activation and repression The human glucocorticoid receptor (hGR) complementary DNA has been sequenced[1,2] and shown to be functionally active[3] Interestingly, sequence analysis of the receptor showed it to be related to the product of the v-*erb-A* oncogene product of avian erythroblastosis virus (AEV)[4] This led to the proposal that the steroid receptors and the *erb-A* oncogene products share a common primordial archetype and that the *erb-A* proto-oncogene products may also be proteins that bind to DNA enhancer elements Recent characterization of the human oestrogen[5,6], chicken progesterone[7,8] and human aldosterone (J Arriza, C W and R M E, unpublished data) receptors further support these conclusions

Accordingly, we started characterizing the human c-*erb-A* proto-oncogene even though its functional identification could not be ensured During the progress of these studies, advances were made in detailing the functional domains of the glucocorticoid receptor[3] which indicated that the hGR hormone binding domain was unusually large, encompassing the carboxy-terminal 300 amino acids This entire region has distant but significant similarity to the carboxy terminus of v-erb-A which therefore focused our attention on classes of molecules that might exert transcriptional regulatory effects similar to those of steroid hormones

The molecular mechanism of thyroid hormone stimulation of gene expression may be similar to that outlined for steroids[9] Thyroid hormone is present in all chordate species examined and exerts profound effects on development and differentiation, such as metamorphosis in amphibians[9] Like steroids, thyroid hormones may enter cells by passive diffusion and bind to high affinity nuclear receptors which in turn mediate a rapid and selective activation of gene expression[10,11] Evidence favouring this hypothesis has come largely from studies of the induction of growth hormone and its messenger RNA in the somatotroph of the rat anterior pituitary and in a number of related rat somatotrophic cell lines[12,13] Thyroid hormones rapidly increase the transcription of the growth hormone gene in these cells[14 15] The increase in transcription is accompanied by increased levels of nuclear thyroid hormone–receptor complexes, is time- and concentration-dependent, and is independent of protein synthesis[16-18]

The similarity of steroid and thyroid hormone actions led us to examine the possibility that the *erb-A* protein may itself be the thyroid hormone receptor We first isolated and characterized a cDNA for human c-*erb-A* The sequence predicts a 456 amino-acid polypeptide containing a cysteine/lysine/arginine-rich region similar to the putative DNA-binding domain of steroid hormone receptors and a carboxy-terminal region distantly related to the steroid binding domain Using a functional assay developed for analysing the hormone binding properties of cloned steroid receptors[2], we demonstrated that the translation product from the human c-*erb-A* cDNA possesses intrinsic thyroid hormone binding activity, characteristic of the native thyroid hormone receptor molecule

Characterization of c-*erb-A* cDNAs

To isolate a human c-*erb-A* cDNA, a 500-base pair (bp) *Pst*I DNA fragment isolated from a region of the AEV genome containing only the v-*erb-A* gene[19] was used as a ^{32}P-labelled probe to screen two human placenta cDNA libraries Two overlapping λgt10 cDNA clones were obtained by screening two independent libraries of ~10^6 phage recombinants each The restriction maps were deduced for each of the cDNA clone *Eco*RI inserts from pUC8 subclones, pheA4 and pheA12 (Fig 1*a*) Nucleotide sequence analysis of these overlapping 1 5 kilobase (kb) cDNA clones revealed that the composite sequence contains a long open reading frame of 456 amino acids with a presumptive initiator methionine codon at nucleotide number 301 and a terminator codon at 1,669 in the sequence (Fig 1*b*) Seven codons upstream of the ATG is an in-frame terminator TAA providing support for the initiator methionine, although another methionine found 26 codons downstream makes this assignment tentative No consensus polyadenylation addition signal (AATAAA, ref 20) is discernible in the 27 nucleotides between the terminator and poly(A) tract in pheA12

A predicted polypeptide of relative molecular mass 52,000 ($M_r = 52$K), encoded within the human c-*erb-A* cDNA translational open reading frame, shares 82% amino acid identity with the region downstream from the viral *gag* sequences[21] in AEV No gaps in the amino acid comparison were revealed The human c-*erb-A* amino acid sequence is homologous with the viral protein beginning at viral amino acid residue 37 (Fig 2) The carboxy-terminus of c-*erb-A* differs from that of v-*erb-A* amino acid sequence similarity of the two polypeptides terminates at residue 445 of c-erb-A and residue 380 of v-erb-A (Fig 2)

Alignment of the human c-*erb-A* nucleic acid sequence with that of v-*erb-A* shows that ~74% of the human gene is identical to the viral gene in the region of amino acid homology (nucleotides 563–1636 in c-*erb-A*, data not shown) These comparisons, coupled with previous data describing other human *erb-A* genes mapping to chromosome 17 (refs 22–24), indicate that the human placenta c-*erb-A* gene we have isolated is distinct One of the two chromosome 17 *erb-A* genes (both of which we propose to call hc-*erb-A*α) has 82% similarity with the v-*erb-A* gene by nucleotide sequence and 89% by amino acid identity[24], There-

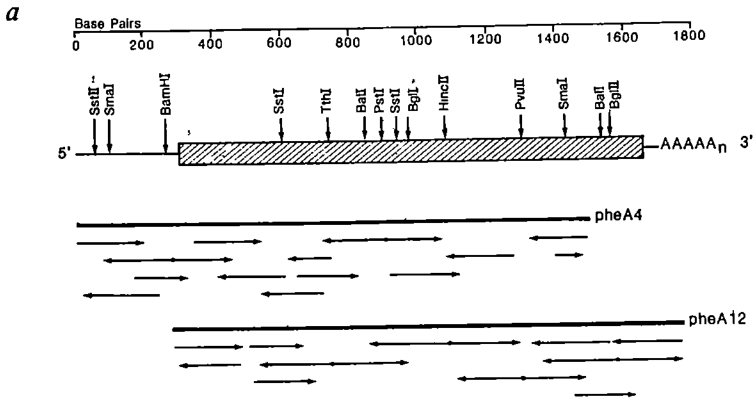

Fig. 1 Restriction map and sequencing strategy (*a*) and nucleotide and predicted amino acid sequence (*b*) of human placenta c-*erb-A* cDNA *a*, Orientations of the two subclones pheA4 and pheA12 relative to the composite restriction map Common restriction endonuclease cleavage sites are above the linear map Thin lines, untranslated sequences, hatched box, *erb-A* coding region, arrows, DNA fragments sequenced *b*, Nucleotide sequence of the composite *erb-A* cDNA is presented in the 5' to 3' orientation The translational open reading frame related to the viral erb-A protein[21] is shown above the nucleotide sequence Adenosine residues (~130) are found at the 3' end of pheA12 Numbers above the translated sequence indicate amino acid residues and nucleotide numbers are on the right of the sequence **Methods** Recombinant phage (~10^6) from each of two human placenta λgt10 cDNA libraries[44] were screened using a nick-translated[45] 500-bp *Pst*I fragment isolated from pAEV-11 (ref 19) The hybridization mixture contained 50% formamide, 1× Denhardt's, 5× SSPE, 0 1% sodium dodecyl sulphate (SDS), 100 $\mu g\ ml^{-1}$ denatured salmon sperm DNA and 10^6 c p m ml^{-1} of ^{32}P-labelled *Pst*I fragment (specific activity = 1×10^8 c p m μg^{-1}) Duplicate nitrocellulose filters were hybridized at 37 °C for 18 h, washed three times for 20 min each in 0 1× SSC, 0 1% SDS (1×SSC = 150 mM NaCl, 15 mM trisodium citrate) and autoradiographed at −70 °C with an intensifying screen Two hybridization-positive clones were isolated, subcloned into the *Eco*RI site of pUC8, and sequenced by the chemical cleavage method[46]

fore, the placenta c-*erb-A* cDNA, which we propose to call hc-*erbAβ*, is more distantly related to the viral *erb-A* gene than the hc-*erbAα* genes

Amino acid sequence comparisons between the viral and cellular *erb-A* protein products and the glucocorticoid receptor indicate graded levels of homology with the carboxy-terminal half of the hGR (Fig 2) The highest degree of similarity is found in a cysteine-rich sequence of 65 amino acids beginning at c-*erb-A* amino acid residue 102 (ref 4) There is 47% amino acid identity in the comparison with the hGR and 52% identity when c-*erb-A* is compared with the human oestrogen receptor (hER) amino acid sequence (Fig 2) We have proposed that this region of the hGR represents the DNA binding domain[4] Mutagenesis and expression studies have provided direct evidence for its role in transcriptional activation[3] Regions downstream from the cysteine-rich domain, which correspond to the hormone binding domain, contain reduced yet significant (17%) homology to the hGR and hER as found previously with the viral *erb-A* product[4-6]

Multiple *erb-A* genes

Hybridization of restriction endonuclease-digested human placenta DNA with a labelled DNA fragment derived from the cysteine-rich region of the c-*erb-A* polypeptide (Fig 1*a*,*b*) pro-

Fig 2 Amino acid sequence comparison between the carboxy-terminal portions of the v-*erb-A* oncogene product, the human placenta c-*erb-A* polypeptide and the human glucocorticoid and oestrogen receptors Translated amino acid sequences for both the v-*erb-A* protein (upper sequence) and the human placenta c-*erb-A* polypeptide (second sequence) were compared by aligning matching residues A computer program for the concurrent comparison of three or more amino acid sequences[47] was used to align c-*erb-A*, human glucocorticoid receptor (hGR third sequence from top)[2] and human oestrogen receptor (hER, bottom sequence)[5] carboxy-terminal amino acid sequences, on the basis of progressive evaluation of selected segments from each sequence Amino acid residues matched in at least three of the polypeptides are boxed Amino acid matches between the two erb-A polypeptides are indicated by an asterisk above the top sequence in each column Amino acid identities between the steroid receptors are designated by crosses below the sequences Hyphens, gaps inserted to maximize the no of matches in the comparison Cysteine residues conserved between the four polypeptides printed white-on-black

duced two bands in every digestion with the exception of *Pvu*II (Fig 3*a*). The greater intensity of the 9 4 kb-band suggested that it contains two hybridizing DNA fragments When the hybridization conditions were relaxed, additional bands were observed in the products of each enzyme digestion For example, two faint bands of 5 1 and 3 6 kb were seen after *Pst*I digestion (Fig 3*b*) The hybridization probe contains a single internal *Pst*I site (Fig 1*a*) which probably explains the increased number of *Pst*I bands detected with this probe

Similar high-stringency hybridization experiments were performed using a 260 bp *Eco*RI-*Bam*HI fragment from the 5' untranslated region of pheA4 (Fig 1*a* and data not shown) Two hybridizing DNA fragments were detected with all restriction enzymes providing further support for the existence of two related c-*erb-A* genes No additional DNA bands were seen when the hybridization was performed under relaxed conditions using this probe (data not shown) We conclude that there are two closely related hc-*erb-Aβ* proto-oncogenes and a third, less similar one, in the human genome

Laser-sorted chromosomes were prepared from human lymphoid cells[25], bound to nitrocellulose filters and hybridized under non-stringent hybridization and washing conditions using the 1 5-kb *Eco*RI insert from pheA4 (Fig 3*c*) This probe detected only human chromosome 3-specific DNA and suggests that the three c-*erb-Aβ*-related genes are chromosomally linked, although we cannot strictly exclude the possibility that the non-stringently hybridizing *erb-A* gene maps in another chromosome Interestingly, another steroid receptor/*erb-A* genomic fragment has recently been identified by characterizing the integration site for hepatitis B virus in a human hepatocellular carcinoma[26] This locus has also been mapped on human chromosome 3 suggesting that the *erb-A* genes may be closely linked

Expression of c-*erb-A* genes

Northern blots hybridizing cytoplasmic poly(A)-containing RNAs, isolated from various human cell lines or human term placenta, with a 650-bp *Bam*HI-*Pst*I fragment from pheA4 (Fig 1*a*) revealed a single RNA species of 2,000 nucleotides that is most abundant in HeLa and MCF-7 cells (Fig 4*a*) The size of the mRNA indicates that we have isolated a nearly full-length c-*erb-A* cDNA HT1080 cells contain a small amount of the 2-kb transcript while it is undetectable in IM-9 cells Human placenta appears to contain multiple species of 5, 3 and 2 5 as well as 2 0 kb RNA It is unclear whether the multiple placenta bands represent nuclear precursors, or mature mRNAs from a single gene, or the products of other *erb-A* genes

The protein products of the human c-*erb-A* cDNA were characterized by *in vitro* translation A cDNA containing the entire c-*erb-A* coding region was inserted into the *Eco*RI site of the expression vector pGEM3 in both orientations Capped RNA transcripts synthesized by T7 polymerase from these templates were used to programme protein synthesis in rabbit reticulocyte lysates and the ^{35}S-methionine-labelled products were separated on SDS-polyacrylamide gels[27] Proteins with M_r of 55, 52, and 35K were detected when peA101 DNA (*erb-A* sense transcripts) was used as template (Fig 4*b*, lanes 3 and 4) but not when peA102 DNA (*erb-A* antisense transcripts) was used (Fig 4*b*, lane 2) The 55 and 52K products may correspond to polypeptides initiating translation at methionines 1 and 27, respectively (Fig 1), while the 35K product may be a proteolytic breakdown product

Thyroid hormone binding

Structural similarity of the steroid ligands as well as the partial amino acid sequence homology (40%) between the carboxy termini of the hGR and hER (which specify the hormone binding domains, ref 28) support the hypothesis that the steroid receptors comprise a family of regulatory proteins The more distant

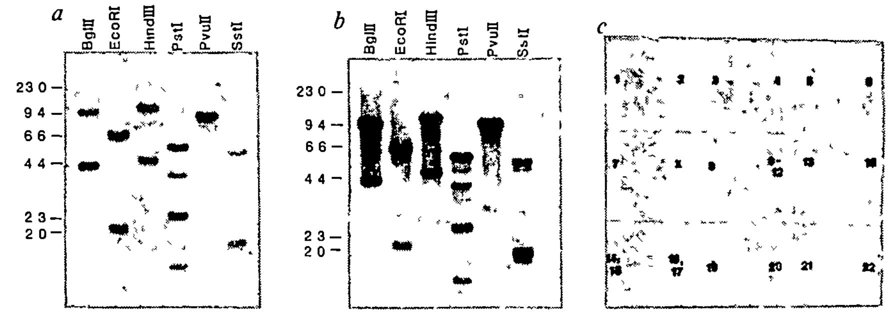

Fig. 3 Southern analysis and chromosome mapping of human placenta DNA with c-*erb-A* DNA probes. *a*, Human term placenta DNA was digested with restriction endonucleases and products were separated on a 0.8% agarose gel. DNAs were transferred to nitrocellulose paper[48] and hybridized in 50% formamide, 5× SSPE, 1× Denhardt's, 0.1% SDS, 100 μg ml^{-1} salmon sperm DNA with the 450-bp *Sst*I fragment from pheA4 which was nick-translated to a specific activity of 5×10^{8} c.p.m. μg^{-1}. The filter was washed in 0.1× SSC, 0.1% SDS at 60 °C and exposed to X-ray film at −70 °C with an intensifying screen. Lambda *Hin*dIII DNA markers (size in kb) are aligned to the left of the autoradiogram. *b*, Analysis of placenta DNA using the same c-*erb-A* probe as in *a* under non-stringent hybridization conditions. A parallel blot containing the same samples was hybridized as in *a*, except that 35% formamide was used. The hybridized filter was washed in 2× SSC, 0.1% SDS at 55 °C and exposed to X-ray film as described above. *c*, Chromosome mapping of human c-*erb-A* genes. Human lymphocyte chromosomes were separated by laser cytofluorometry[25] and probed using the non-stringent hybridization conditions described in *b*, but with the 1.5 kbp *Eco*RI insert from pheA4 as probe.

homology between the carboxy terminus of c-*erb-A* and the steroid receptors suggested that *erb-A* proto-oncogenes probably do not encode steroid receptors, but is consistent with the hypothesis that *erb-A* may respond to other molecules. We have shown that *in vitro* translation can be used as a means to characterize hormone binding activity of cloned steroid receptors[2]. Accordingly, this assay was employed to identify the putative c-*erb-A* ligand.

Steroid and thyroid hormones exert their effects through fundamentally similar mechanisms. To address the possibility that erb-A may be the thyroid hormone receptor, the *in vitro* translation products were mixed with ^{125}I-3,5,3′-triiodo-L-thyronine (^{125}I-T_3) in a hormone binding reaction[29]. Non-specific hormone binding was determined by adding a 500-fold molar excess of cold T_3 to parallel samples. Remarkably, the mixture containing the 55 and 52K polypeptides (peA101) acquired ^{125}I-T_3 binding whereas the anti-sense RNA-programmed lysates (peA102) had only background binding. Hormone binding was sensitive to proteases but not nucleases (data not shown). Affinity of T_3 for the cloned *erb-A* protein was determined by Scatchard analysis (Fig. 5*a*). A K_d value of 5×10^{-11} M was obtained, which is virtually identical to the T_3 binding (6×10^{-11} M) in HeLa cell nuclear extracts (data not shown).

Specific analogues of thyroid hormones have characteristic competition patterns for T_3 binding to the native thyroid hormone receptor. We determined whether the *erb-A* product synthesized *in vitro* shared the same intrinsic hierarchy of affinities for a range of natural and synthetic thyroid hormones. Competition of ^{125}I-T_3 binding was most effectively achieved with 3,5′, 3′-triiodothyroacetic acid (TRIAC) which inhibited 50% of ^{125}I-T_3 binding at 300 pM (Fig. 5*b*). In addition, L-thyroxine (Fig. 5*b*), D-T_3 and reverse T_3 (3,3′,5′-triiodo-L-thyronine) competed more poorly than T_3 (Fig. 5*c*), while 100 μM vitamin D_3, aldosterone, cortisol, testosterone, progesterone or oestradiol did not compete (data not shown), consistent with the biochemical properties of the rat thyroid hormone receptor[29–31].

High salt (0.4 M KCl) HeLa cell nuclear extracts contained thyroid hormone (^{125}I-T_3) binding activity, while none was found in cytoplasmic or low-salt (0.1 M KCl) nuclear extracts (data not shown). Competition of thyroid hormone binding in the nuclear extracts was quantitatively similar to that of lysates containing c-erb-A made *in vitro* (compare Fig. 5*b* and *d*). Furthermore, thyroid hormone binding using 0.4 M KCl nuclear extracts from IM-9 cells, which contain undetectable levels of c-*erb-A* mRNA (Fig. 4, lane 4), is negligible when compared with similar HeLa extracts (data not shown). These results provide direct evidence that c-erb-A is the thyroid hormone receptor.

Conclusions

The data in this report provide three criteria that identify the c-*erb-A* product as the thyroid hormone receptor. First, the overall structural homology of c-erb-A to steroid hormone receptors suggests that erb-A is likely to be a ligand-responsive regulatory protein. Second, the expressed protein product has the same intrinsic hierarchy of affinities for natural and synthetic thyroid hormones as the native receptor. Third, the molecular weights of erb-A *in vitro* translation products are similar to the photo-affinity-labelled rat thyroid hormone receptor[39]. The identity of erb-A as the thyroid hormone receptor could be further sub-

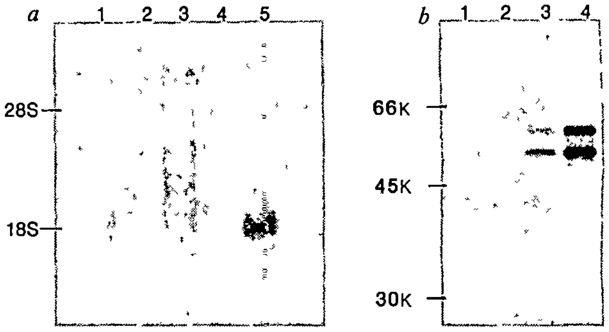

Fig. 4 Human c-*erb-A* expression. *a*, Northern analysis of RNAs from human cell lines and human placenta. Cytoplasmic poly(A)-containing RNA (12 μg) from HeLa, MCF-7 and IM-9 cells, or total poly(A) RNAs from HT1080 or placenta, were separated on a 1% agarose gel containing formaldehyde, transferred to nitrocellulose[49] and probed using a nick-translated 650-bp *Bam*HI-*Pst*I pheA4 fragment. Cytoplasmic RNAs were isolated from the cell lines using isotonic buffer and 0.5% NP40, while the placenta RNAs were extracted from fresh tissue using guanidine thiocyanate[50]. Lane 1, HeLa; lane 2, HT1080; lane 3, human placenta; lane 4, IM-9; lane 5, MCF-7. *b*, Synthesis of erb-A polypeptides *in vitro*. The ^{35}S-methionine-labelled products synthesized using T7 polymerase-catalysed RNA transcripts were separated on a 12.5% SDS-polyacrylamide gel which was fluorographed (EN^{3}HANCE, NEN). Lane 1, control (without mRNA); lane 2, peA102 (anti-sense RNA, 4 μl); lane 3, peA101 (sense RNA, 1 μl); lane 4, peA101, (4 μl RNA). Sizes of protein standards: bovine serum albumin, 66.2K; ovalbumin, 45K and carbonic anhydrase, 31K.

Methods. The *Eco*RI insert from pheA12 which contains the entire coding region of c-*erb-A* was inserted into the *Eco*RI site of pGEM3 (Promega Biotec) in both orientations. Plasmid DNAs peA101 and peA102 were linearized with *Hin*dIII, purified on 0.8% agarose gels and used as templates for T7 polymerase-catalysed synthesis of RNAs *in vitro*[2]. After P60 chromatography, total nucleic acid material (2 μg) was used to programme protein translation in a rabbit reticulocyte lysate system (Promega Biotec) with ^{35}S-methionine (25 μCi, 1100 Ci mmol^{-1}, NEN) final volume 25 μl.

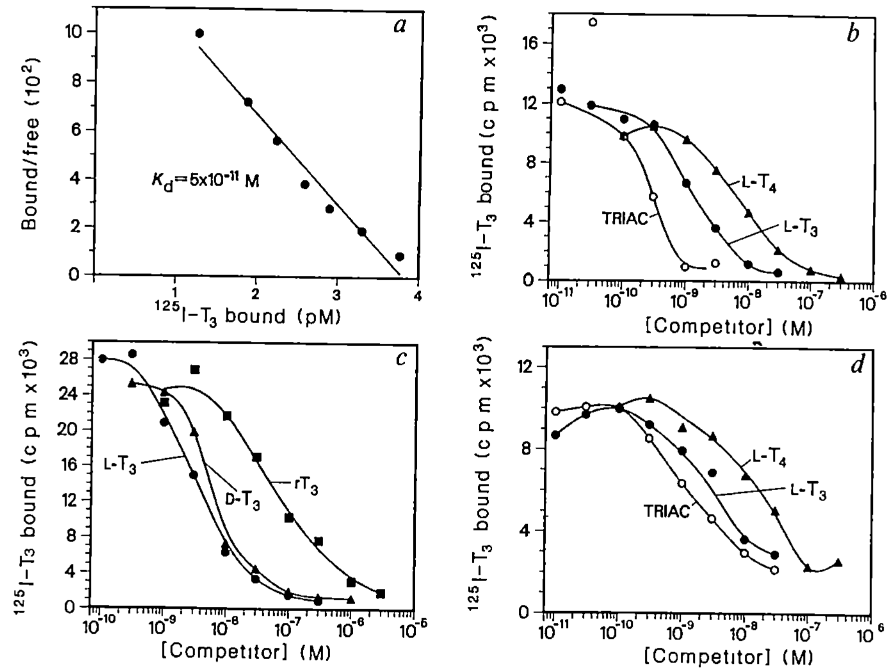

Fig 5 Thyroid hormone binding to erb-A polypeptides synthesized *in vitro* *a*, Scatchard analysis of ^{125}I-T$_3$ binding to the erb-A polypeptides made *in vitro* The erb-A polypeptides (2 μl from the *in vitro* translation mixture in a total volume of 2 ml) were assayed for specific thyroid hormone binding activity using hydroxylapatite to measure the amount of bound and free labelled hormone at different concentrations of ^{125}I-T$_3$ as described[51] *b*, Competition of thyroid hormone analogues for ^{125}I-T$_3$ binding to erb-A polypeptides synthesized *in vitro* Samples (2 μl) from the peA101(sense strand)-programmed reactions were used in ^{125}I-T$_3$ standard binding reactions[29] with increasing concentrations of unlabelled thyroid hormone or analogues to compete with labelled hormone, Specifically bound thyroid hormone is plotted against concentration of competitor compound *c*, Competition of triiodothyronine isomers for ^{125}I-T$_3$ binding to erb-A polypeptides synthesized *in vitro* Binding reactions were performed as above adding increasing concentrations of T$_3$ isomers Thyroid hormone bound to erb-A is plotted on the ordinate *d*, Competition of thyroid hormone analogues for ^{125}I-T$_3$ binding to 0 4 M KCl HeLa cell nuclear extracts HeLa cell nuclei were extracted with a buffer containing 0 4 M KCl (ref 29) The protein extract (25 μg) (determined by Bio-Rad protein assay) was mixed with 0 6 nM ^{125}I-T$_3$ in standard binding reactions with increasing concentrations of thyroid hormone and analogues[29 30]

Methods Labelled ^{125}I-3,3′, 5-triiodo-L-thyronine (NEN, 2,200 Ci mmol^{-1}, 0 3 nM final) was mixed with erb-A polypeptides synthesized in the *in vitro* translation mixture (described in Fig 4) in T$_3$-binding buffer (0 25 M sucrose, 0 25 M KCl, 20 mM Tris-HCl (*p*H 7 5), 1 mM MgCl$_2$, 2 mM EDTA, 5 mM dithiothreitol (DTT))[29] at 0 °C for 2 h in a final volume of 250 μl Specific hormone binding was determined by adding a 1,000-fold excess of unlabelled hormone and assayed by counting radioactivity eluting in the excluded volume from a Sephadex G-25 fine (Pharmacia) 0 9×4 0 cm column[29]

stantiated by demonstrating its transcriptional regulation of T$_3$-responsive genes such as the growth hormone gene

Analysis of the hGR and hER has revealed the proteins to be composed of a series of functional domains[2-4,32-35] These include a cysteine-rich region which contains structural similarity to a repeated cysteine-rich sequence found in *Xenopus* 5S gene transcription factor IIIA and other transcriptional regulatory proteins[36,37] as well as carboxy-terminal sequences, which encode the steroid-binding domain[3,4,38] Extension of this analogy to the thyroid hormone receptor would predict its hormone binding region to be localized near the carboxy-terminal end of the molecule (Fig 6) Putative DNA binding sequences would be found in the cysteine-rich region (Fig 6) where DNA binding properties of the hGR and hER appear to be localized (refs 3, 38, S Hollenberg and R M E , unpublished data)

Thyroid hormone receptor and oncogenesis

Expression of the v-*erb-A* product in avian erythroblasts is required for maintenance of the fully transformed phenotype[40-43] Chickens infected with viruses lacking the v-*erb-A* gene display a less virulent disease, while *in vitro* these infected erythroblasts differentiate spontaneously and grow only with complex media supplements Cells infected with *erb-A*$^+$/*erb-B*$^+$ virus, however, have an increased capacity for self-renewal and display a less differentiated phenotype Structural alterations of the v-*erb-A* protein could give rise to a product exerting aberrant properties of growth control For instance, changes at the carboxyl terminus might affect thyroid hormone binding activity, as has been shown for the *β* form of the human glucocorticoid receptor, resulting in a constitutively active molecule[2-4], where changes abolish steroid binding activity Insertional mutants in this domain also inactivate steroid binding properties[3] However, deletion of the hormone binding region gives rise to a constitutively active receptor indicating that this domain plays a modulatory role in transcriptional activation (V Giguere and R M E , unpublished data) These data lead us to predict that v-erb-A is unlikely to bind hormone and is rather a constitutively active form of the thyroid hormone receptor The identification of erb-A as the thyroid hormone receptor provides the first direct evidence of a causative involvement of enhancers and their binding proteins in oncogenic transformation

A superfamily of regulatory genes

Similarity of the steroid receptors with the v-*erb-A* oncogene product was sufficient to allow us to propose that both have evolved from a primordial receptor gene[4] Two surprising results have emerged from the studies presented here The first is that

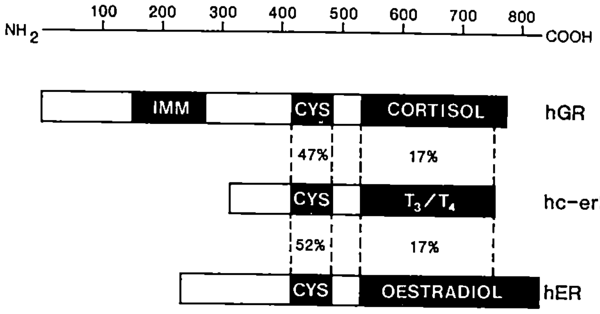

Fig 6 Schematic comparison of the steroid and thyroid hormone receptors Amino-acid sequences of the receptor molecules aligned in Fig 2 are represented schematically CYS, cysteine-rich region encoding the putative DNA binding domain found in the receptor proteins (Cys-rich region residues are c-erb-A, 102–169, hGR, 421–486, hER, 185–250) Cortisol, oestradiol and T$_3$/T$_4$), hormone binding regions in the carboxyl termini, IMM, immunogenic region of the human glucocorticoid receptor Numbers separating boxes, percentage amino acid identities between the receptor species in the intervals between the vertical broken lines, hGR, human glucocorticoid receptor, hER human oestrogen receptor, hc-erb-A*β*, human thyroid hormone receptor

the occurrence of a family of *erb-A* proto-oncogenes implies the existence of one or more other molecules closely related to the thyroid hormone receptor Physiological studies have not predicted the existence of a second class of thyroid hormone receptors and thus the characterization of this family may shed new light on mechanisms of developmental and homeostatic regulation The second surprising observation from these results is the close kinship of the thyroid hormone receptors with the steroid hormone receptor family This relationship indicates that these molecules may all be part of a superfamily of regulatory proteins that have arisen over evolutionary time to match the increasing developmental and physiological demands of more complex eukaryotes Thus, the putative identification of the *erb-A* protein as the thyroid hormone receptor leads to new insight into these issues and should provide an important tool for analysis of the molecular basis of transcriptional activation by regulatory proteins

We thank Dr Michael G Rosenfeld for discussions, Gail Cerelli and Kevin Murakami for technical help during the initial phase, Drs Bart Sefton and Richard Heyman for suggestions, and Drs Russell F Doolittle and Mark Johnson for carboxy-terminal sequence alignments C W thanks Robin for helpful discussions We also thank Marijke ter Horst for artwork and help in the preparation of the manuscript C W and R L are research associates of the Howard Hughes Medical Institute C T is a pre-doctoral trainee, supported by a training grant to the Department of Biology, University of California, San Diego R M E is an investigator of the Howard Hughes Medical Institute This work was supported by grants from the NIH and the Howard Hughes Medical Institute

Rotational period of comet Halley

R. L. Millis & D. G. Schleicher

Lowell Observatory, 1400 West Mars Hill Road, Flagstaff,
Arizona 86001, USA

The rotational period of the nucleus of comet Halley is a basic datum which must be accurately known if the vast collection of observations of this comet recently obtained from spacecraft and ground-based observatories are to be correctly interpreted. Sekanina and Larson, who have studied the morphology of the comet's coma, find a period near 2.2 days, as do investigators associated with the Planet-A, Vega 1 and Vega 2 imaging experiments[1-4]. Others, however, have reported significantly different values, or have been unable to find clear evidence of periodicity in their data[5-7]. We report here the results of ground-based photometry of comet Halley carried out during March and April 1986 which indicate that the rotational period of the comet is, in fact, near 7.4 days.

During an extended photometric study of comet Halley during the 1985-86 apparition, two lengthy observing runs were scheduled on the 0 61-m Lowell-Tololo telescope at Cerro Tololo Inter-American Observatory (CTIO) in March and April of 1986 The March run (4-18 March) was timed to span the encounters of the Vega, Planet-A, and Giotto spacecraft with the comet, while the April run (29 March-19 April) covered the time of the comet's closest approach to Earth Of the 37 nights on which we had use of the telescope during the March and April runs, 36 were, at least in part, photometric Consequently, much high-quality photometric data were obtained While our main aim was to measure production rates of various gases and dust and to determine their variation with heliocentric distance, it quickly became apparent that the comet was undergoing sizeable night-to-night changes in activity

The observations were made using a conventional single-channel photometer equipped with pulse-counting electronics Interference filters, mostly chosen from the standard IAU set[8], were used to isolate emission bands of OH, NH, CN, C_3, CO^+, and C_2 along with continuum regions at 3,650 and 4,845 Å Observations were made with the comet's apparent photocentre centred in the entrance aperture of the photometer Each observation typically consisted of two or three 10-s integrations on the comet minus a sky measurement made several degrees away Extinction corrections were determined nightly and have been applied in the standard fashion The observed intensities were then transformed to absolute fluxes by reference to nightly observations of several standard stars Finally, the underlying

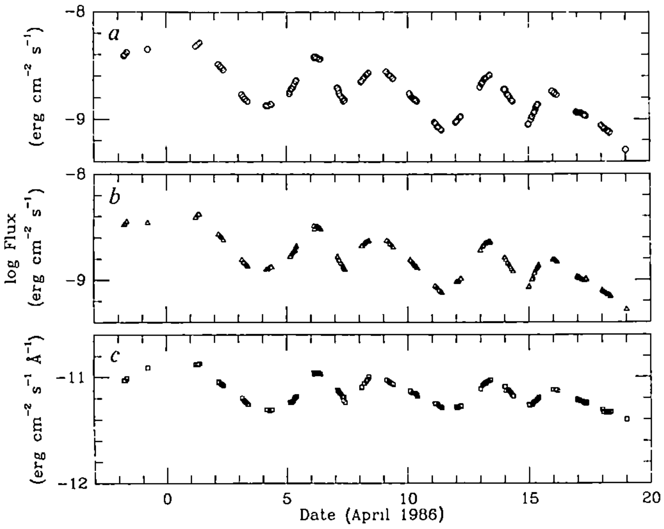

Fig. 1 Brightness variations in the inner coma of comet Halley seen during April 1986 in the light of emission bands of *a*, C_2 (5,140 Å), *b*, CN (3,870 Å), *c*, in a continuum passband at 3,650 Å.

continuum within the emission-band filters, based on the continuum-band results, was subtracted.

Figure 1 shows the flux from comet Halley through selected passbands measured during the April run. These observations were made with a photometer entrance aperture of 39-arc s radius. Light curves of essentially identical shape were recorded through the other filters and with entrance apertures of different sizes. The observational uncertainty in each plotted point is comparable to or less than the size of the point. It is evident from a brief inspection of Fig. 1 that the brightness of the central region of the coma was varying by a factor of ~4 on a timescale of a few days.

For brevity, we will discuss only observations made in a single passband centred on an emission band of C_2 at 5,140 Å and with the same 39-arc s radius aperture. This aperture, which is the one we used most frequently, had a corresponding radius at the nucleus of the comet which ranged between 33×10^3 and 12×10^3 km during March and April 1986. To remove, at least to first order, the effects of the variation in aperture size at the comet, we have converted the observed C_2 fluxes to column densities and then to production rates assuming a Haser model. While one might quibble with the applicability of the Haser model to comet Halley, the results presented here concerning the short-period variability of the comet in no way depend on the strict validity of this model.

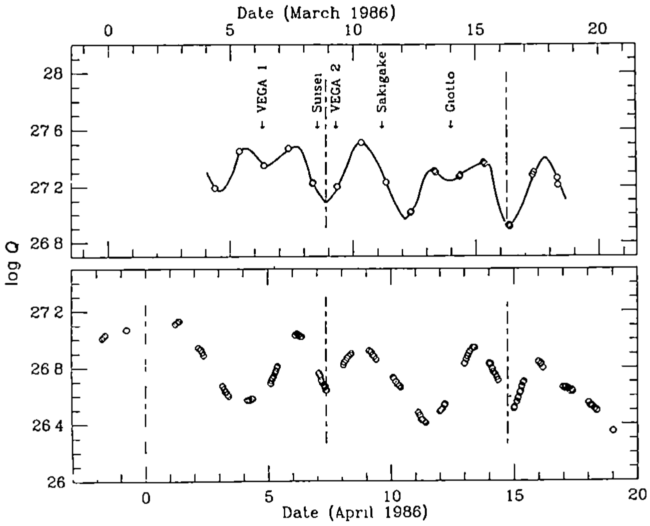

Fig. 2 Production rate of C_2 as a function of time in March and April 1986. Arrows mark the times of the various spacecraft encounters. Dashed lines identify corresponding minima in March-April

The observed production rates of C_2 in comet Halley during March and April are plotted as a function of time in Fig. 2. Because the comet was observable for most of each night in April, the continuity of the data from that month is sufficiently good that there is no question about the timescale of the variation. Furthermore, it is evident from even a casual inspection of Fig. 2 that the photometric behaviour of the comet between 3.5 and 11 April was repeated almost exactly between 11 and 18.5 April, indicating that the light curve has two maxima per cycle with a period near 7.5 days. During the March run, the period was evidently similar, but the light curve had a more complex shape than in April. Contemporaneous International Ultraviolet Explorer (IUE) observations with the FES (fine error sensor) camera[9] agree with the shape of the mean March light curve as we have drawn it through the observed points.

In addition to the periodic variation, a steady secular decrease in the production rate of C_2 can be seen in Fig. 2 throughout March and April. This secular change, which presumably resulted from the decreasing insolation as the comet moved away from the Sun, has been removed from the data before performing the period search described below.

A search for periodicity in the observations was performed by applying the method of phase dispersion minimization separately to the March and April data. This method[10] is ideal for application to data such as those in Fig. 2 because it makes no assumptions about the shape of the light curve. In this method, the data are phased according to an assumed period and then divided into a number of phase bins, *M*, spanning the full phase interval. The variance within each bin, $S_j^2(j=1, M)$, is computed, and then the overall variance for all bins S^2 is calculated from

$$S^2=\frac{\sum (n_j-1)S_j^2}{\sum n_j - M}$$

where n_j is the number of data points in the *j*th bin. A statistic, θ, defined as the ratio of S^2 to the variance of the total data set, is computed. This process is repeated for a broad range of trial periods. If the assumed period is very different from the true period, the phased data will constitute a scatter diagram and $\theta = 1$. At a true period, however, θ will reach a local minimum.

In Fig. 3*a*, we have plotted θ as a function of period for the April data. In computing θ, the data were divided into five phase bins. Note that over the entire range of periods from 1 to 10 days, the deepest minimum is at ~7.4 days. There is no significant minimum near 2.2 days. Figure 3*b*, *c* shows a plot of θ against period at higher resolution for the March and April observations. For the April data, a sharp minimum is found at 7.37±0.07 days. The quoted uncertainty is estimated. Because of less complete sampling of the light curve in March as compared with April, the minimum centred at 7.41 days in the θ versus period plot has a broad, flat bottom. The uncertainty in the period determination based on the March data alone is estimated to be ~0.1 day. Another minimum at 3.9 days was found in the analysis of the March observations. However, that period, which is almost exactly four times the sampling interval, can be shown to be an artefact of the period-finding method.

Composite light curves for March and April, constructed by phasing the data according to the 7.37-day period, are plotted in Fig. 4. We have adopted this single period for the two data sets because the two values determined above are the same to within their estimated errors and because we feel that the April run provided the more accurate value. The superposition of

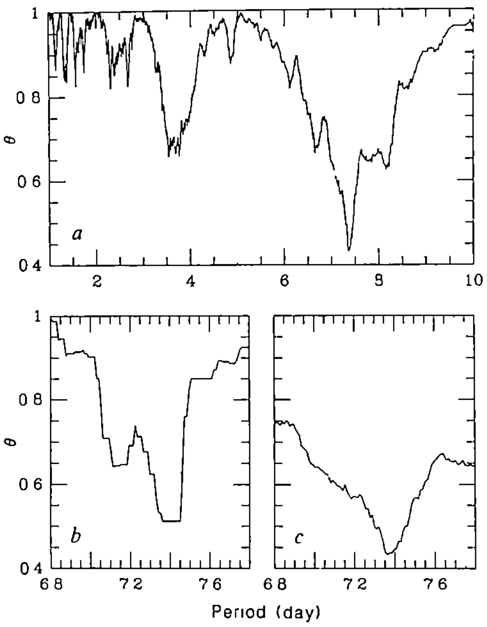

Fig 3 *a*, The statistic θ plotted as a function of period for the data between 29 March and 19 April At a true period, θ is expected to show a local minimum By far the deepest minimum seen here corresponds to a period near 7 4 days *b* And *c*, the same type of plot as described above shown at expanded time resolution for the 4-18 March and 29 March-19 April data, respectively

successive cycles is surprisingly good Certainly, one would not expect the light curve of an active comet to be as repeatable as that of an inert object like an asteroid, and, indeed, the form of comet Halley's light curve did evolve between the two observing runs The abscissae in Fig 2 have been located so that the March data are placed relative to the April data, as if shifted forward in time by four cycles of the 7 37-day period Note that the minima marked by the dashed lines nearly coincide in phase In fact, the primary change in the light curve between March and April is the absence in April of the first hump of the broad maximum seen in March A change of this character in the shape of the light curve could easily occur if a localized region of activity on the comet's nucleus became dormant or, at least, substantially decreased its output during the last 2 weeks in March The underlying periodicity of the light curve, on the other hand, would be unaffected

We believe that the most natural explanation of the periodic variations that we have observed in the brightness of comet Halley's inner coma is an up-and-down fluctuation in the comet's overall level of activity as surface regions of greater or lesser volatility are brought into sunlight by the rotation of the nucleus The observed period of the brightness variations is, therefore, identified with the synodic period of rotation of the cometary nucleus If this interpretation is correct, the observed period would be expected to have decreased by ~0 1 day between March and April if the sense of rotation is the same as that of the orbital motion Such a change is consistent with our observations However, our period determinations are not sufficiently accurate to unequivocally confirm a change of this magnitude

Comet Halley's light curve is seen to have basically two maxima and two minima per rotation While not required, such a light curve is not unexpected given the shape of the nucleus as revealed by the Vega and Giotto imaging experiments[11,12] Comet P/Arend-Rigaux, whose nucleus also has been shown to be elongated, has a two-peaked light curve[13]

Of the previous attempts to ascertain the rotational period of comet Halley, some, like the present study, were based on ground-based photometry, albeit with much less continuous observational coverage[6,7] The results have been inconclusive Whipple[5] and Sekanina and Larson[1,2] have taken a different approach based on the morphology of the coma as recorded primarily on ground-based photographs Sekanina and Larson find a rotational period near 53 h Investigators analysing observations from the Japanese ultraviolet imager experiment and the Vega 1 and 2 imaging experiments also have reported periods near that value[3,4] However, pending a fuller description of the spacecraft results, we are unconvinced that their period determination should be accepted as firm The ultraviolet imager on the Planet-A Suisei spacecraft detected several brief Ly α flashes over a period of months However, the total interval is extremely undersampled Continuous coverage has been published for only one 2 4-day interval, during which several flashes were seen If several flashes can occur per cycle and if the light curve has not been shown to repeat over even two successive cycles, then determination of a unique period would seem difficult The Vega 1 and 2 investigators have measured the rotational period of comet Halley's nucleus by examination of images obtained during two 40-min observation periods separated by 3 days While we in no way wish to denigrate the remarkable accomplishment that the Vega 1 and 2 images represent, they are of low resolution It seems questionable that a truly unique period determination could be based on those images

Given the strong periodicity at 7 4 days in the photometric data reported here and the absence in these observations of evidence for other periods, we believe that previous determinations of the rotational period of comet Halley should be re-examined We can think of no source of the variations present in our data other than rotation of the nucleus If this interpretation of the photometric data is correct, then we can predict the relative orientation of the nucleus at the times of the encounters of the comet with the Planet-A, Vega 1 and 2, and Giotto spacecraft The times of these encounters are indicated by arrows in Fig 2 We expect that at the Vega 1 and Giotto encounters the orientation of the nucleus with respect to the Sun was very similar At the time of the Vega 2 encounter, however, roughly the opposite side of the nucleus was facing sunward Suisei and Sakigake were not equipped to image the nucleus

Current theory holds that jets, spirals and other detailed features in cometary comae are visible only in the continuum reflected by the dust particles. It has generally been thought that these features could not be seen in the emission bands of the typical neutral species, at least in part because the neutral parent molecules expand in directions perpendicular to any linear feature in a time short compared with that required to travel the length of the features. Consequently, the daughter species normally observable at optical and ultraviolet wavelengths are produced by dissociations that take place far from the point of origin of the gas. Here we present images of comet Halley taken in the light of CN emission, that show prominent jets extending to >60,000 km from the nucleus and lasting several weeks. We interpret these images as jets of submicrometre particles, perhaps the organic 'CHON' particles detected from spacecraft, from which the CN is directly produced.

During comet Halley's post-perihelion phase, we carried out observations with the 24-inch planetary patrol telescope at Perth Observatory, using a CCD (charge-coupled device) camera system which is one of two developed jointly with S. M. Larson (the system will be described elsewhere). The present observations were made in April, when the comet was near opposition, with an effective focal ratio of 5.4 and a scale of 1.8 arc s per pixel on the CCD chip. The filter set is a duplicate of the IAU standard filters distributed to the photometry and polarimetry net of the International Halley Watch and the photometric calibration was done with exactly the same techniques as used by that net.

The comet was imaged several times each night in various emission-band and continuum filters. Jets were visible in real time on the television monitor in the raw images taken with the CN filter. These features are not visible in nearly simultaneous images taken in the reflected continuum, nor are they coincident with the sharper, shorter features seen by shift-difference processing in nearly simultaneous broad-band images processed by S. M. Larson (personal communication). The jets seen in CN light appear to be of much higher contrast, broader, longer and in totally different orientations.

Figure 1 shows the processing that has been applied to all subsequent images. At the upper left is a direct image taken on 23 April, corrected by bias subtraction and flat field and smoothed with a three-point triangle (Hanning function). In all images presented here, north is at the bottom and east is at the left. This image, only a portion of the total frame from the CCD, is 5 arc min = 10^5 km square. The existence of three jets is clear: they extend roughly south, east and north-west but curve substantially into spirals. Images in the continuum have not yet been subtracted from our images in CN but photometric calibration indicates that the continuum will be negligible except in the few pixels nearest the nucleus. For processing, the image was extracted to an (r, θ) plot as shown at the lower left, in which radius is the ordinate and azimuth is the abscissa. To enhance the jets each horizontal line of the (r, θ) representation was renormalized to the maximum and minimum values along that line. The result is shown at the lower right, in which the shape of the jets is much more clearly seen than in the unnormalized representation. This plot was then converted back to the conventional image format at the upper right. This procedure was followed for all of the images shown in Fig. 2. All images were also scaled to the same physical size in kilometres at the comet.

It is clear that the jets have a spiral shape due to the rotation of the nucleus; despite the first impression, however, the view is not along the polar axis. Figure 2 shows a series of images from 16–23 April. During this period, the northern rotation pole (that is, the angular momentum vector) as defined at the 1910

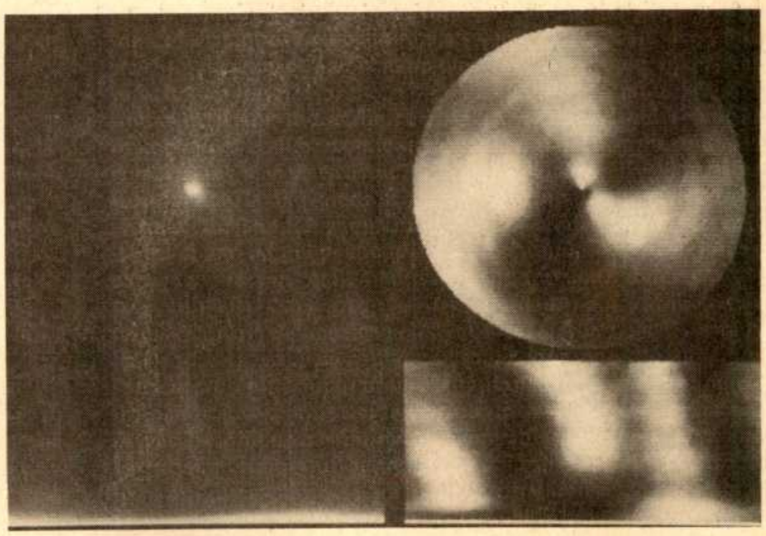

Fig. 1 Image processing steps applied to all images. The upper left panel is the cometary image extracted from the original CCD image, no. 81 in Table 1. Bias subtraction and flat-field corrections have been applied. The lower left panel is a radius (r) against polar angle (θ) display of the original image. The radial distance increases upward and the position angle on the sky is the abscissa varying from west through north. The lower right panel is a contrast enhancement of the lower left panel. The enhancement is such that each line, a circle in the original image, has been scaled between the minimum and maximum of the display. This effectively removes all radial variation. The upper right panel is the enhanced (r, θ) plot converted back to an (x, y) coordinate system.

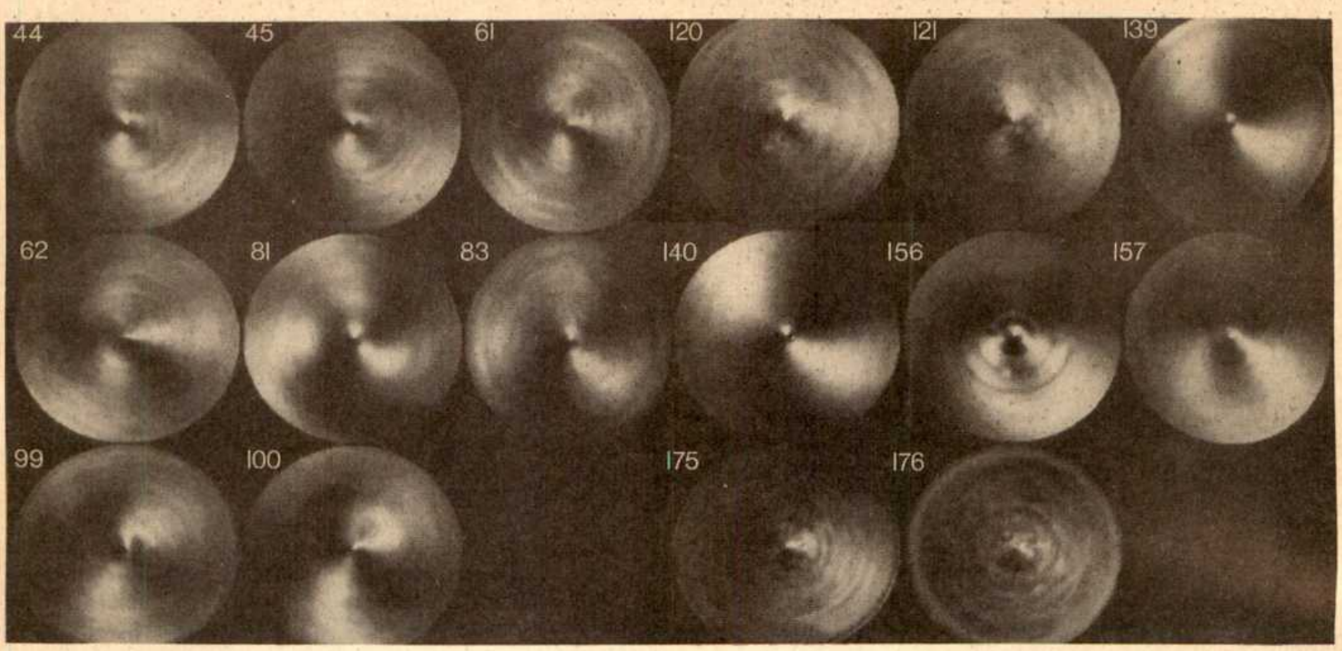

Fig. 2 The radially enhanced images for eight days at two frames per day. The details of the exposures are given in Table 1. Time increases with image number. Each image has undergone the enhancement process described in the text and Fig. 1.

apparition[1] was pointing nearly southward as seen on the sky and changed from nearly in the plane of the sky at the beginning of the period to pointing towards Earth, ~20° out of the plane of the sky. Preliminary indications from the present apparition are that the current rotation pole may differ by ~20° from that determined in 1910[2,3]. The position angle of the Sun varied across the entire south-west quadrant, from 199° on 16 April to 272° on 29 April.

Identification of jets persisting from one day to the next is dependent on the assumed period of rotation. Examination of the series of images, many of which are shown in Fig. 2, shows that there are at least three and, if the rotation period is 2.17 days[1], probably five jets involved. It is possible that other rotation periods may be consistent with the pattern, perhaps requiring fewer jets. A more detailed analysis will follow.

The ratio of the ejection velocity of the material in the jets to the rotational velocity of the nucleus can be estimated from the slope of the jets in the (r, θ) plots. With the assumptions that the spiral patterns are due to projected helices and that the rotational period is 2.17 days[1], the ejection velocity is $\sim\frac{2}{3}$ km s^{-1}, comparable to that inferred from spacecraft[4,5]. This scales inversely as the rotational period, but is only an order of magnitude estimate. Again, detailed modelling will follow.

The fact that the jets are so pronounced in the light of CN has significant implications for the formation of CN radicals. Figure 3 shows brightness profiles as a function of azimuth for several different radii in the image shown in Fig. 1: these represent horizontal cuts through the lower right panel and they show a range of 720° in azimuth (two full rotations) to exhibit more clearly features that would be at the edge of a plot showing only one rotation. The full width at half maximum (FWHM) of the CN distribution is ~45° at a radius of 30,000 km, which corresponds to a linear FWHM of 24,000 km. The emission from the jet must be due to fluorescence rather than, for example, prompt emission (emission immediately following dissociation into the excited $B^2\Sigma$ state) because a typical CN radical will fluoresce many times before leaving the jet, whereas it can produce only one photon by prompt emission. The half width at half maximum of the parent, then, must be $\leqslant$3,000 km, much too narrow for the parent to be a neutral gaseous species released from the nucleus. If we take the FWHM of the parent species to be 3,000 km at a radial distance of 30,000 km and take $\frac{2}{3}$ km s^{-1} as the ejection velocity, the maximum transverse velocity corresponds to a temperature near 5 K. In the absence of a confining mechanism for the jets, the inescapable conclusion is that the jets are composed of dust grains and that the CN is either dissociated directly from molecules on the surfaces of the grains or dissociated from parent molecules that have a very short ($\tau < 1{,}000$ s) lifetime before photodissociation and that vaporize from the grains. Although this result was quite surprising to us, Bobrovnikov[6,7] reported such jets in comets Halley and Westphal, and Wurm and Mammano[8] discussed the rapid formation of CN in expanding haloes.

Why do we not see these dust grains in the images taken in the continuum? As pointed out by Sekanina[3], the grains are probably no larger than 0.1 μm, so they would not be seen in the reflected continuum, which is dominated by much larger grains. In fact, the spacecraft that passed through the coma of Halley detected many more very small particles than had been expected[4,5,9,10,11]. It seems likely that the CN is being dissociated directly from the grains because estimates of the dissociation lifetimes of a variety of plausible parents for CN are all $>10^4$ s (ref. 12). It is tempting to suggest that the CN comes from the organic 'CHON' particles found by the spacecraft[13,14].

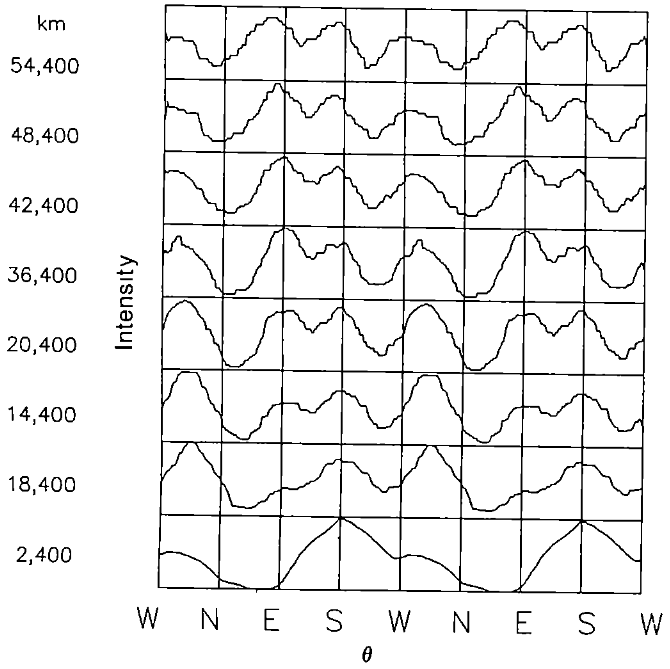

Fig 3 Plot of normalized intensity against azimuth for eight discrete radii projected on the sky, labelled by the value of projected radius These plots are horizontal cuts through the lower right panel of Fig 1, image no 81 in Table 1

A very crude estimate of the fraction of the CN in the comet that is produced in this way can be obtained by examination of the unnormalized version of Fig 3 At radii of 10,000–20,000 km, the fraction of the column density of CN that is in the jets is ~10–15% Because the high ejection velocity of CN on photodissociation causes the CN in the jets to diffuse rapidly into the background, it is not unreasonable to assume that this represents the total fraction of all CN that comes from the grains

It is not yet clear whether the CN jets discussed here and attributed to dissociation from grains are related to the fluctuations in CN detected from the spacecraft Levasseur-Regourd *et al.*[15] reported that an excess of CN (relative to a vectorial model) was detected near the nucleus by the Optical Probe Experiment on Giotto, they attributed this excess to prompt emission In addition to the excess emission that they reported near the nucleus, examination of their Fig 2 shows fine structure in the CN flux, particularly an enhancement near log $r = 3$ 6, which is clearly above the noise and might be due to passage of Giotto through jets such as those reported here Similarly, Moreels *et al*[16] have reported that the three-channel spectrometer on Vega 2 also detected an excess of CN near the nucleus The spacecraft data clearly merit a more detailed examination in the context of additional ground-based data Our own images from the time near the spacecraft encounters do not show any prominent jets in CN, but those images have not yet been examined in sufficient detail to rule out the presence of such jets It does seem at least plausible that the excess CN seen by the spacecraft experiments is provided by dissociation from the organic grains, as we have suggested for the CN in the jets reported here If our hypothesis is correct, similar structures should be visible in images taken in the light of other radicals composed of 'CHON', provided that they have sufficient contrast with the background Preliminary studies of images in the light of C_2 indicate that the jets are present but weaker, because of the strong contribution by the continuum which does not exhibit jets

M F A'H and S H. thank the staff of the Perth Observatory and the University of Western Australia for hospitality and assistance during the course of these observations, particularly Arie Verveer for his technical assistance, and the government of Western Australia for their support through these institutions We thank Zdenek Sekanina and Nalin Samarasinha for several helpful discussions regarding the geometry of the jets and Z S for pointing out that the dust grains must be very small, Steve Larson for comparing these CN jets with the ones used in modelling the nuclear rotation, and for designing and building the CCD system, many individuals for comments regarding the relationship to the organic grains, Jurgen Rahe for pointing out the earlier work on CN structures, and Barbara Boothman for programming the algorithms for the (r, θ) extraction and providing general assistance with the computing The CCD system was constructed with financial support from the International Halley Watch office at the Jet Propulsion Laboratory The observing programme was supported by NASA grant NSG 7322 and NSF grant INT 85-14707 to the University of Maryland

Note added in proof The existence of submicrometre 'CHON' particles in comets has recently been discussed by Greenberg[17] as a consequence of accretion of interstellar grains

Nitric acid cloud formation in the cold Antarctic stratosphere: a major cause for the springtime 'ozone hole'

Paul J. Crutzen* & Frank Arnold†

* Max Planck Institute for Chemistry, PO Box 3060,
D-6500 Mainz, FRG
† Max Planck Institute for Nuclear Physics, PO Box 103980,
D-6900 Heidelberg, FRG

Large depletions in stratospheric ozone were first reported by Farman *et al.*[1] at Halley Bay (76° S), and confirmed by satellite observations[2]. Chubachi[3] gives a detailed account of ozone decreases and temperatures in the lower stratosphere during the spring of 1982 at 69° S. There is now evidence[2] for annual declines in total ozone by ~6 and 3% in regions of total ozone minima and maxima, respectively, from September to mid-October since the late 1970s. We propose here a chemical mechanism for the formation of the ozone hole. It involves removal of gaseous odd nitrogen by ion- and/or aerosol-catalysed conversion of N_2O_5 and $ClONO_2$ to HNO_3 vapour, followed by heteromolecular HNO_3–H_2O condensation, leading to HNO_3–H_2O aerosols. At an altitude of 17 km, these processes start at temperatures below 205±5 K, well above the condensation temperature of pure water vapour. We propose that the absence of gaseous odd nitrogen and catalytic methane oxidation reactions driven by sunlight in early spring lead to large OH concentrations which rapidly convert HCl to ClOX. Catalytic reactions of ClOX and BrOX cause drastic ozone destructions and can account for the springtime 'ozone hole' first observed by Farman *et al.*[1]. By our model the depletion would be

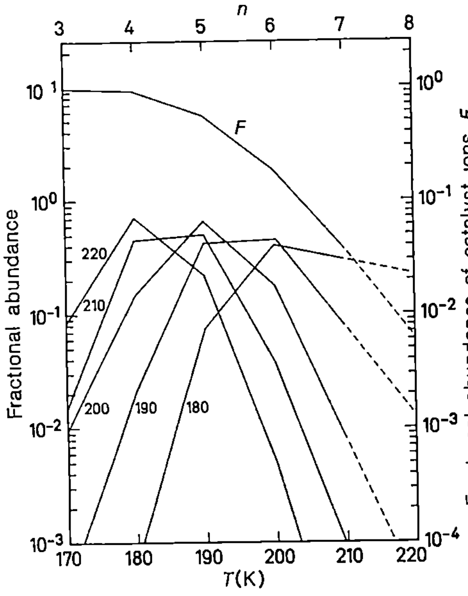

Fig. 1 Size distributions of $H^+(H_2O)_n$ cluster ions (upper abscissa and left ordinate) for an altitude of 17 km, an H_2O-vapour volume mixing ratio of 3×10^{-6} and temperatures of 180, 190, 200, 210 and 220 K (thermodynamical data of Lau *et al.*[17]) Also shown is the fraction *F* of $H^+(H_2O)_n$ ions (lower abscissa and right ordinate) with $n\geq6$ that may serve as catalysts

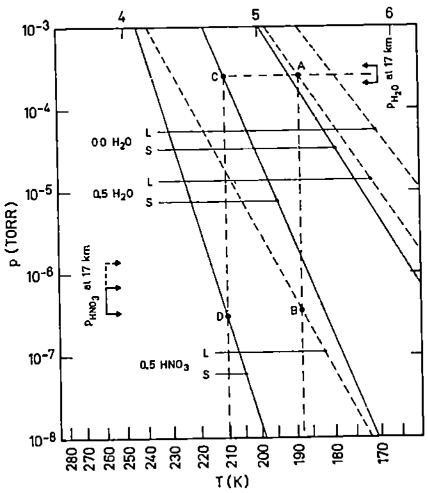

Fig. 2 Equilibrium saturation vapour pressures of H_2O and HNO_3 over solid (solid curves) and liquid (broken curves) H_2O-HNO_3 mixtures with HNO_3 mass fractions of 0.5 and 0.0 (pure H_2O) Also shown are partial pressures for H_2O and HNO_3 as observed in the background atmosphere around 17 km altitude[29] Condensation temperatures for liquid mixture (points A and B) and solid (points C and D) mixtures are about 188 K and 211 K respectively For liquid and solid H_2O ($f_2=0.0$) condensation temperatures are about 179 K and 191 K respectively

mainly due to emissions of industrial organic chlorine compounds. Arctic regions may also become affected. The depletion lasts while HNO_3, but not HCl, is incorporated in the particles in the temperature range 205±5 K to 192 K.

Farman *et al*[1] connected the ozone decrease with the extremely cold temperatures and stable dynamics of the lower stratosphere and also proposed that the depletion was due to the increasing transfer of industrial chlorine compounds to the stratosphere This idea was later developed by McElroy *et al*[4] and Solomon *et al*[5] McElroy *et al*[4] consider reactions between ClO and BrO Their scheme requires the absence of NO and NO_2 from the stratosphere, brought about by reactions of N_2O_5 and $ClONO_2$ on the surfaces of the stratospheric cloud particles observed[6,7] in polar regions

$$N_2O_5+H_2O\rightarrow2HNO_3,\ ClONO_2+H_2O\rightarrow ClOH+HNO_3 \quad (1,2)$$

and furthermore the conversion of most HBr to BrO_x, and most HCl to ClO_x For the latter assumption, however, they do not present a mechanism Solomon *et al*[5] assume that efficient reactions of $ClONO_2$ and HCl occur in polar clouds

$$ClONO_2+HCl\rightarrow Cl_2+HNO_3 \quad (3)$$

leading to the catalytic reaction chain

$$OH+O_3\rightarrow HO_2+O_2,\ Cl+O_3\rightarrow ClO+O_2 \quad (4,5)$$

$$ClO+HO_2\rightarrow ClOH+O_2,\ ClOH+h\nu\rightarrow Cl+OH \quad (6,7)$$

$$\text{net} \quad 2O_3\rightarrow3O_2 \quad (D1)$$

The efficiency of the heterogeneous reactions (1)-(3) for stratospheric conditions has not been measured, so the above studies are speculative

To explain the observations we present a chemical mechanism, involving the following steps (i) conversion of NO_x to N_2O_5 during polar night

$$NO+O_3\rightarrow NO_2+O_2,\ NO_2+O_3\rightarrow NO_3+O_2 \quad (8,9)$$

$$NO_3+NO_2(+M)\rightarrow N_2O_5(+M) \quad (10)$$

(ii) formation of HNO_3 by ion- and /or aerosol-catalysed conversion of N_2O_5 and $ClONO_2$ at temperatures ≤215-210 K, (iii) heterogeneous, heteromolecular condensation of HNO_3 vapour with H_2O giving rise to stratospheric cloud particles and depletion of gaseous HNO_3 at temperatures ≤205±5 K, (iv) efficient hydroxyl radical formation by cosmic ray ionization and ozone photolysis, amplified by photochemical methane oxidation reactions after sunlight returns to the polar regions, (v) conversion of HCl to ClOX, and HBr to BrOX, by reaction with OH, (vi) ozone destruction through ClOX and BrOX catalysis

Conversion of N_2O_5 and $ClONO_2$ to HNO_3 and the depletion of gaseous NO_x and HNO_3, which are possible only at low temperatures, are key elements in our mechanism as they prevent

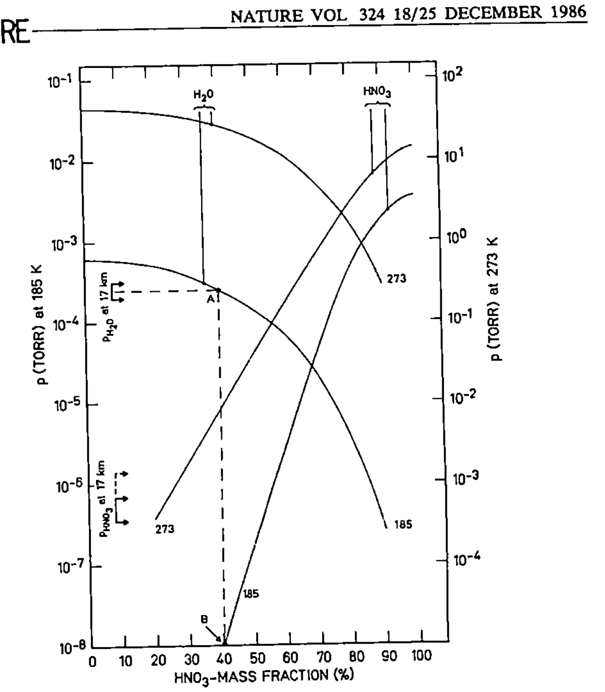

Fig 3 Equilibrium saturation vapour pressures of H_2O and HNO_3 over liquid H_2O-HNO_3 mixtures against the HNO_3-mass fraction f_2 for temperatures of 273 K and 185 K Also shown are partial pressures of H_2O and HNO_3 as observed in the background atmosphere around 17 km altitude Both sets of curves show the lowering of equilibrium vapour pressures of H_2O and HNO_3 over those of the one-component systems At 185 K and $f_2=40\%$ large supersaturation of gaseous HNO_3 occurs and co-condensation of HNO_3 and H_2O takes place

OH removal by the otherwise most important catalytic reaction cycle

$$OH + HNO_3 \rightarrow H_2O + NO_3, \quad NO_3 + h\nu \rightarrow NO_2 + O \qquad (11, 12)$$

$$NO_2 + OH(+M) \rightarrow HNO_3(+M) \qquad (13)$$

$$\text{net} \qquad 2OH \rightarrow H_2O + O \qquad (H1)$$

Conversion of N_2O_5 and $ClONO_2$ to HNO_3 via (1) and (2) may be catalysed by ions and/or aerosols. The ion-catalysed mechanism involves an H_2O molecule as a reaction partner, contained in a cluster ion[8-10]. Atmospheric ambient ions present at ~17 km, the centre of the height region of interest, are $H^+(H_2O)_n$, $H^+(CH_3CN)_m(H_2O)_n$, and $NO_3^-(HNO_3)_m(H_2O)_n$ as was found from recent balloon-borne mass-spectrometer measurements[11-13]. For $H^+(H_2O)_n$ ions, for example, N_2O_5 conversion may proceed via

$$N_2O_5 + H^+(H_2O)_n \rightarrow HNO_3 + H^+(H_2O)_{n-1}HNO_3 \qquad (1a)$$

$$H^+(H_2O)_{n-1}HNO_3 + H_2O \rightarrow HNO_3 + H^+(H_2O)_n \qquad (1b)$$

becoming exothermic only for $n \geq 6$. Ions of the type $NO_3^-(HNO_3)_m(H_2O)_n$ may be even more efficient catalysts as extra energy is gained due to stronger clustering of HNO_3 formed by the N_2O_5 reaction[10]. However, to serve as catalysts both positive and negative ions must be hydrated enough. This is possible only at low atmospheric temperatures. Fig 1 shows calculated relative abundances of the members of the $H^+(H_2O)_n$ family and also the fraction F of $H^+(H_2O)_n$ ions with $n \geq 6$. Taking the calculated F values, lower limits to the N_2O_5 lifetime, t_i, against ion-catalysed conversion can be estimated. For a total ion concentration of ~10^4 cm^{-3} and a typical rate coefficient for an ion-molecule reaction of 2×10^{-9} cm^3 s^{-1} one obtains $t_i \geq 5 \times 10^4/F$ s. Hence, at temperatures below about 215 K, t_i may become shorter than one month. It should be mentioned, however, that exothermicity does not necessarily guarantee a large reaction coefficient and t_i may therefore be larger than this. For a more detailed discussion of ion processes see ref 10.

Conversion of N_2O_5 and $ClONO_2$ on aerosols is rather uncertain as the reaction probability per collision, γ, is not well known. The lifetime t_{AC} of a gaseous molecule against collision with aerosols in the background atmosphere at ~17 km is ~10^4 s and thus the reaction time t_A becomes t_{AC}/γ. To make t_A one month, $\gamma = 2 \times 10^{-3}$ is required, which is much larger than γ measured[14] for concentrated sulphuric acid at 300 K.

In the cold Antarctic stratosphere, however, the aerosol content may become much larger than in the background stratosphere as found from solar extinction measurements[6,7]. This excess aerosol, termed polar stratospheric clouds (PSCs) has previously[7] been explained in terms of H_2O condensation alone. Here we shall argue that heteromolecular condensation of HNO_3 and H_2O occurs and leads to a great increase of the aerosol mass and surface area, which, in turn, may accelerate aerosol-catalysed N_2O_5 and $ClONO_2$ conversion, and more importantly leads to a depletion of HNO_3 vapour. Figure 2 shows extrapolations of measured[15] equilibrium saturation vapour pressures e_1 (H_2O) and e_2 (HNO_3) over an HNO_3-H_2O mixture with an HNO_3-mass fraction $f_2 = 0.5$. The extrapolations contain considerable uncertainties, especially for the solid state[10]. The case $f_2 = 0.5$ was chosen as this mixture gives the highest condensation temperature. Also shown in Fig 2 are partial pressures for a_1 (H_2O) and a_2 (HNO_3) as found in the background atmosphere around 17 km altitude[29]. The procedure to derive such conditions is illustrated in Fig 3 for liquid mixtures and a temperature of 195 K. The condition for heteromolecular condensation ($e_1 \leq a_1$ and $e_2 \leq a_2$) for $T =$ 185 K is met at f_2 near 40%. For this mixture $e_1 = a_1$, but $a_2 \gg e_2$,

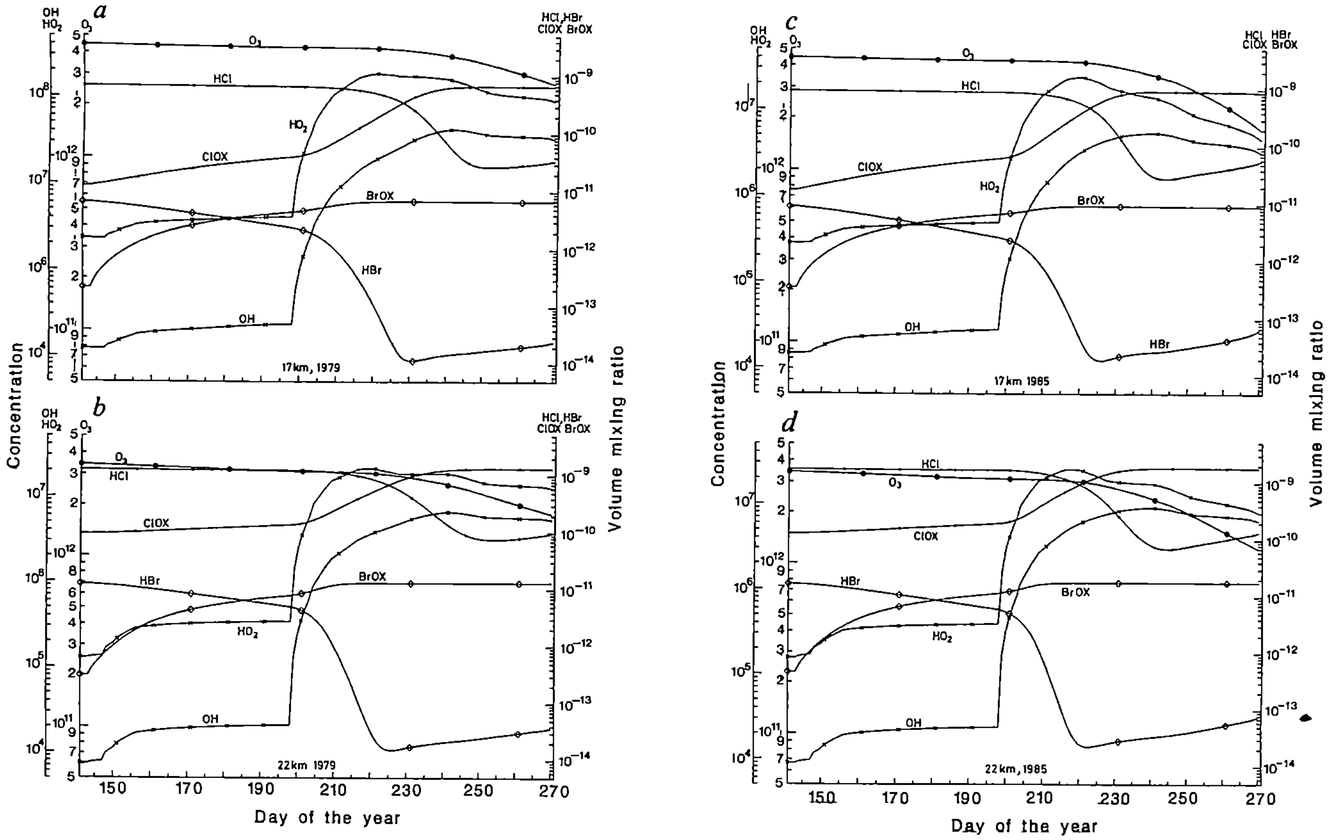

Fig. 4a, b, calculated concentrations (molecules cm^{-3}) at noon, of OH and HO_2 (first scale on the left) and of O_3 (second scale on the left), and volume mixing ratios of HCl, ClOX, HBr and BrOX (right scale). Polar night conditions at 70° S, here defined as Sun below horizon for 24 h period, lasted from 22 May (day 142) to 18 July (day 198). It was assumed that from day 147 nitric acid became incorporated in the polar stratospheric clouds. Calculations were performed for two altitudes, 17 km (a) and 22 km (b), and estimated conditions for the year 1979. c, d, Similar calculations as a, b, for 1985.

so that gaseous HNO_3 condenses out. This lowers both e_1 and the atmospheric partial pressure of HNO_3 and increases e_2, so that about 1.5 times more H_2O than HNO_3 molecules condense out. Because $a_1 \gg a_2$, the resulting atmospheric pressures of HNO_3 will be much reduced, while those of H_2O are hardly affected.

An inspection of Fig. 2 reveals that the condensation temperature T_c for a liquid mixture with $f_2 = 0.5$ (points A and B) is about 188 K. For solid mixture one obtains $T_c = 211$ K (points C and D). A further cooling below T_c by only 3-4 K would be sufficient to deplete 50% of the HNO_3 vapour, giving rise to an increase of the aerosol mass and surface area by factors of about 100 and 20 respectively. Condensation of pure H_2O vapour, which becomes possible only at temperatures below about 191 K (solid) to 179 K (liquid), gives rise to an additional strong increase of the aerosol mass. The heteromolecular HNO_3-H_2O condensation mechanism proposed here offers an explanation for recent extinction measurements[6,7] showing a strong increase of the stratospheric total extinction at 1 μm wavelength over Antarctica as temperatures fall below about 205 K, which is close enough to 211 K considering the uncertainty of vapour pressure extrapolations and height distribution of the aerosol. Below about 191 K also other trace gases, particularly HCl, may become incorporated in aerosols[10]. With the increased aerosol surface, aerosol-catalysed N_2O_5 and $ClONO_2$ conversion may become important, depending on γ. However, ion-catalysed processes may be more efficient. It is possible that they are the missing source of HNO_3 in the polar winter stratosphere required in recent studies[10,18].

Another ion process which has a role in polar-night stratospheric chemistry is hydroxyl radical formation by ion chemistry driven by galactic cosmic rays. The rate of this ion-assisted OH formation is one to two OH molecules per ionization event or ~40-80 OH molecules $cm^{-3}\,s^{-1}$ at high geomagnetic latitudes. Because the galactic cosmic ray ionization rate varies with solar activity, an 11-yr modulation will be induced. A more detailed discussion of ion and aerosol processes will be given in ref. 10.

Modelling of stratospheric photochemical processes is complex and all details cannot be discussed here. Our model uses a standard set of chemical reactions[20,21]. To emphasize the effects of chemistry alone, we adopted a very small eddy diffusion coefficient, because the south polar vortex seems to be such a stable dynamic system[22].

When gas-phase NO_x and HNO_3 are removed from the lower stratosphere, the OH radial reacts mainly with CH_4, HCl and HBr

$$CH_4 + OH(+O_2) \rightarrow CH_3O_2 + H_2O, \; HCl + OH \rightarrow Cl + H_2O \qquad (14, 15)$$

$$HBr + OH \rightarrow Br + H_2O \qquad (16)$$

The results of the model calculations shown in Fig. 4, for altitudes of 17 and 22 km for 1979 and 1985, at 70° S, are mainly intended to demonstrate the sensitivity of ozone to odd-nitrogen removal during springtime. They are not close simulations of the exact conditions in the Antarctic. The calculations were started with concentrations obtained with our two-dimensional model. Ozone and temperature data were taken from the measurements[3] made at Syowa (60° S) in 1983. The small jumps in the curves occurring around day 147 indicate the date at which we have assumed that HNO_3 becomes incorporated in the cloud particles. The large changes in concentrations which occur near day 200, about 20 July, mark the return of daytime conditions (Sun above the horizon) for some period during the day. Results are shown for noon. In these calculations ClOX denotes the sum of Cl, ClO, ClOH, Cl_2O_2 and OClO. The last three compounds all dissociate rapidly in daylight, producing ClO_x (= Cl + ClO). BrOX is defined similarly. The stratospheric concentrations of total inorganic bromine were assumed to be 1% of those of inorganic chlorine, which seems to be roughly in agreement with the observations, although the uncertainty is large[23,24].

Besides reaction cycle D1, there are two other catalytic reaction chains that are important in the breakdown of stratospheric ozone during early spring when sunlight has returned to the Antarctic.

$$ClO + BrO \rightarrow Cl + Br + O_2, \; Cl + O_3 \rightarrow ClO + O_2 \qquad (17, 5)$$

$$Br + O_3 \rightarrow BrO + O_2 \qquad (18)$$

$$\text{net} \qquad 2O_3 \rightarrow 3O_2 \qquad (D2)$$

as considered by McElroy *et al.*[4], and

$$ClO + ClO(+M) \rightarrow Cl_2O_2(+M) \qquad (19)$$

$$Cl_2O_2 + h\nu \rightarrow Cl + ClOO, \; \lambda < 350\,\text{nm} \qquad (20)$$

$$ClOO + M \rightarrow Cl + O_2 + M \qquad (21)$$

$$Cl + O_3 \rightarrow ClO + O_2 (2\times) \qquad (5)$$

$$\text{net} \qquad 2O_3 \rightarrow 3O_2 \qquad (D3)$$

as recently introduced by Molina and Molina[25] and R. A. Cox (personal communication). According to Molina and Molina, the photolysis rate of Cl_2O_2 is roughly that of ClOH. The product yield of (20) is still only based on indirect evidence[25]. For (19) we chose the rate expression $k = 6 \times 10^{-33}\,(300/T)^{2.1}\,cm^6\,molecule^{-2}\,s^{-1}$ by R. A. Cox (personal communication).

We note from the results in Fig. 4 that during polar night much HBr can be converted to BrOX by (16). The conversion would be much enhanced if HBr reacted rapidly with NO_3, which seems quite likely. The conversion of HCl to ClOX is less efficient, because (15) is ~1/25 as fast as (16). During polar night, a large fraction of the OH radicals produced by the galactic cosmic rays is lost by reaction with CH_4. The situation changes drastically after sunlight returns, when, starting from low odd hydrogen concentrations, reactions with CH_4 lead to rapid net production of odd hydrogen. The important reactions are

$$CH_4 + OH(+O_2) \rightarrow CH_3O_2 + H_2O, \qquad (14)$$

$$CH_3O_2 + HO_2 \rightarrow CH_3O_2H + O_2 \qquad (22)$$

$$CH_3O_2H + h\nu \rightarrow CH_3O + OH, \; \lambda \leq 350\,\text{nm} \qquad (23)$$

$$CH_3O + O_2 \rightarrow CH_2O + HO_2 \qquad (24)$$

$$\text{net} \qquad CH_4 + O_2 \rightarrow CH_2O + H_2O$$

followed with about 30% probability by

$$CH_2O + h\nu \rightarrow H + CHO, \; \lambda \leq 330\,\text{nm}, \qquad (25)$$

$$H + O_2 + M \rightarrow HO_2 + M \qquad (26)$$

$$CHO + O_2 \rightarrow CO + HO_2 \qquad (27)$$

The net result of the oxidation of one methane molecule by OH is therefore an average net gain of 0.6 odd hydrogen radicals, providing for a rapid buildup of OH radicals until these are also significantly lost by

$$CH_3O_2H + OH \rightarrow CH_3O_2 + H_2O, \; CH_3O_2H + OH \rightarrow CH_2O + H_2O + OH \qquad (28a, b)$$

For the first weeks, the main primary source of OH is production by galactic cosmic rays. Later, the reactions

$$O_3 + h\nu \rightarrow O(^1D) + O_2, \; \lambda \leq 310\,\text{nm}, \qquad (29)$$

$$O(^1D) + H_2O \rightarrow 2OH \qquad (30)$$

become more important, further enhancing the OH concentrations. ClOX is efficiently produced from HCl after the polar night, leading to efficient destruction of ozone mainly through reaction cycle D1 and D3, with some contributions also from the BrO_x/ClO_x cycle D2. The calculations for two altitudes 17 and 22 km, shown in Fig. 4, demonstrate the sensitivity of stratospheric ozone to the perturbations that characterize the springtime Antarctic lower stratosphere, so that the observed trends in ozone removal can be explained by the chemical mechanisms presented above The ozone decay continues as long as most HNO_3 is bound in the stratospheric polar clouds, that is, until the Antarctic stratospheric warming occurs in late September or early October[3,22] Then the evaporation of the polar clouds will reintroduce the various NOX gases into the lower stratosphere through known photochemical processes and most ClOX will be converted back to HCl The decreasing ozone concentrations will delay the springtime solar warming of the lower stratosphere and this could gradually increase the period of unstable photochemistry The ozone depletion will last as long as HNO_3, but not HCl is incorporated in PSCs At an altitude of 17 km this occurs between 205±5 K and 192 K Although less frequent than in the Antarctic, such conditions occur also in the Arctic stratosphere

In this paper we could not present a detailed analysis of all features of the Antarctic ozone hole, because this requires consideration of and access to extensive meteorological, chemical and optical data sets[26] We have, however, clearly shown how in the Antarctic lower stratosphere during winter and springtime unstable photochemical conditions can develop that lead to drastic destruction of ozone Several other complications that are likewise not treated in this paper must be considered in future studies, such as the effects of the major eruptions of volcano El Chichon in 1982, the possibility of gravitational settling of the particles[26], and the reactions of odd hydrogen and other chemical compounds on the particles

To test our chemical mechanism, measurements of odd nitrogen and chlorine gases as well as ambient ions would be very informative No measurements of HNO_3 and HCl have so far been reported in the Antarctic for September–October Available total column NO_2 observations[27,28] agree with the mechanism proposed, but do not provide proof Also laboratory studies of the binary H_2O-HNO_3 system at low temperatures and ion-catalysed reactions are needed

We thank Christoph Bruhl and Barnabas Thwaites for their assistance with the calculations, and Ian Galbally for valuable comments

Are domains in liquid crystalline polymers arrays of disclinations?

Barbara A. Wood & Edwin L. Thomas†

* Polymer Products Department, E I DuPont, Experimental Station, Wilmington, Delaware 19898, USA
† Polymer Science and Engineering Department,
University of Massachusetts, Amherst, Massachusetts 01003, USA

Interaction of mobile disclinations in the liquid crystalline state results in various disclination arrays. The mesophase state of liquid crystalline polymer (LCPs) samples has been assumed to consist of a polydomain texture, each domain having an internal structure of uniform orientation bounded by regions where the molecular director field undergoes reorientation from one domain to its neighbour. However, the detailed nature of the boundary region (in particular whether the molecular director reorients in a continuous or discontinuous fashion) is largely unknown. We have observed groupings of disclinations of alternating sign which resemble Bouligand's serrated wall structure[1] and 'foursomes' of two positive and two negative disclinations which bear a likeness to the 'effective domain' structure recently hypothesized by Marrucci[2] to account for certain rheological aspects of LCPs. The arrangements of disclinations in our thin-film samples give rise to an apparent polydomain texture consisting of regions of uniform molecular orientation bounded by disclinations where the molecular director undergoes continuous rotation about an axis parallel to the disclination lines (Neel walls) The specific disclination arrays observed will be influenced by the molecular weight and stiffness constants of the particular LCP and by the flow history, thickness and boundary conditions of the film[3]; nevertheless, except in the vicinity of the disclination cores, the field of molecular director trajectories throughout the polydomain sample texture is both continuous and translationally parallel.

Due to industrial and academic interest in stiff chain and semiflexible polymer molecules, there have been an increasing number of structural and rheological studies of liquid crystalline polymers in recent years A banded texture is often noted in flow-oriented LCP specimens Donald *et al*[4] have examined the banded structures in detail and have recently shown that annealing transforms the banded morphology into a 'vein' structure which they relate to orientation domains Initial explanations for phenomena such as the yield stress and the three-region viscosity-shear rate curve (two shear-thinning regions separated by a newtonian plateau) have invoked the polydomain concept where, during flow, the domains slide by one another easily at low shear rates At moderate shear rates, the domains are supposed to break up, leaving dispersed domains in matrix of uniform molecular orientation, and, at high shear rates, a continuous monodomain structure is realized[5] A recent theory of Marrucci[2], however, emphasizes the role of disclinations in the rheology of liquid crystalline polymers The fluid is imagined

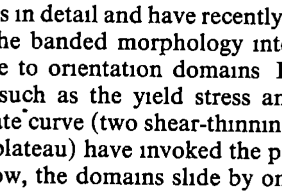

Fig 1 Schematic of an effective domain in a liquid crystalline polymer consisting of an array of four half-integer disclinations Lines indicate the molecular trajectory about the defect lines (●) (from ref 2)

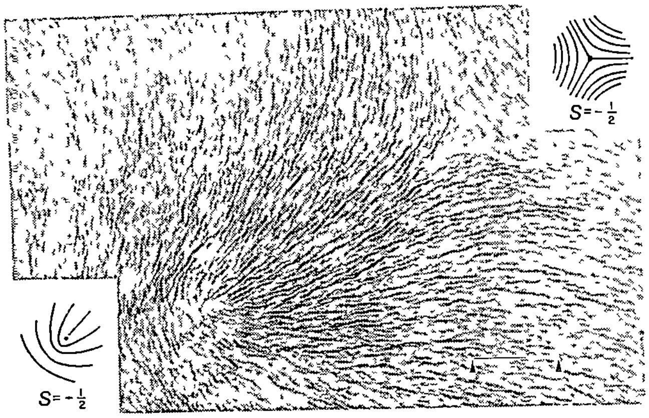

Fig 2 TEM image of disclination dipole in a thermotropic liquid crystalline polymer and schematic (insets) of molecular director trajectories around a positive and a negative half-integer disclination Scale bar, 10 μm

to consist of an assembly of 'effective domains' due to a particular arrangement of disclinations In two dimensions, Marrucci's scheme consists of a group of two positive and two negative half-integer disclinations (Fig 1) This particular array yields an approximately zero average net director orientation over the basic domain and hence zero global sample orientation Moreover, the molecular director changes continuously over the polydomain sample except at the disclination cores Wissbrun[6] has further developed Marrucci's model to allow the size (or number density) of the domains to change during flow, with consequent changes in the rheological characteristics Recent flow visualization experiments using light microscopy have suggested that the flow can both increase[7] and decrease[8] the number of defects in the fluid To date, no detailed experimental observations of the proposed disclination-domain structures have been made

Recent transmission electron microscopy (TEM) studies of alternating rigid/flexible thermotropic LCPs conducted in our laboratory have permitted direct visualization of the molecular director pattern in flow-oriented thin films at a resolution unmatched by previous light micrographs[9] The mesophase texture and defects existing in the polymer melt state are retained by thermal quenching of the polymer fluid to room temperature By annealing the glassy liquid crystalline polymer film above its glass transition but below the melting point, crystalline lamellae grow perpendicular to the local chain axis and effectively 'decorate' the molecular director field throughout the sample

Samples were prepared by annealing of substrate-free oriented thin films of the thermotropic polyester from 1,10-decane *bis*(terephthaloyl chloride) and hydroquinone[9,10] Figure 2 is a TEM image of a region containing two singularities in the field of oriented long, thin crystalline polymer lamellae Electron diffraction proves that the chain axis is normal to the long dimension of the lamellae Thus, the set of lamellar normals represents the set of molecular director trajectories over the sample As was recently pointed out by Frank[11], the lamellar decoration pattern demonstrates that the molecular director field consists of translationally parallel trajectories, that is, families of congruent curves such that the vector joining points of the same slope on any two members of the family is a constant The trajectories of the lamellar normals in the vicinity of each defect corresponds quite well with that expected from the molecular director trajectories associated with 180° disclination lines running perpendicular to the specimen plane The molecular director trajectories about such isolated defects are in good accord with those predicted nearly 30 years ago by Frank[12] Dipoles consisting of a positive and negative 180° disclination at a typical separation of micrometres are frequently observed Apparently, annihilation occurs if pairs of opposite sign disclinations approach each other more closely The core regions of the negative (threefold symmetric) disclination appear bright, which indicates a local thinning of the film, possibly corresponding to a high concentration of chain ends and hairpin molecular folds

In addition to isolated and variously paired disclination dipoles, arrays involving approximately equal numbers of positive and negative disclinations are frequently observed A diamond-shaped group involving two positive and two negative half-integer disclinations have been seen repeatedly (Fig 3*a*) Details of the molecular director trajectories are shown in Fig 3*b* The molecular director pattern is nearly identical to that of the hypothetical "effective domain" structure envisaged by Marrucci (see Fig 1) The groups of four disclinations observed also resemble the 'lozenges' defined by edge dislocations of layers in cholesteric small-molecule liquid crystals as described by Bouligand[1] Groups of two positive and two negative disclinations (although of integer strength) were first drawn by Lehmann in a 1918 monograph[13]

A larger group of disclinations is shown in Fig 4*a* A several square micrometres region of uniform orientation is bounded by a serrated wall of 10 alternating positive and negative disclinations Bouligand's[1] schematic of a serrated wall structure is shown in Fig 4*b* The discrete appearance of domains suggested by the images shown in Fig 3*a* and 4*a* results from observing the field of normals to the molecular director trajectories rather than the trajectories themselves[11] Regions of approximately

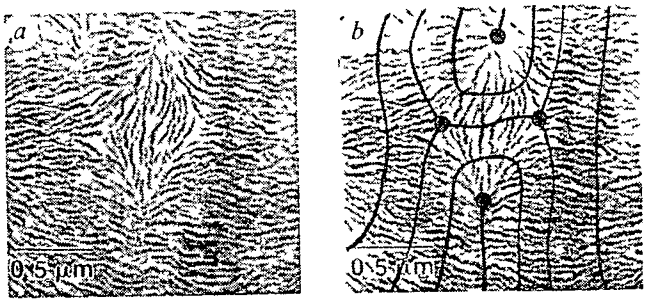

Fig 3 *a*, TEM image and *b*, schematic overlay of lamellar trajectories in a diamond-shaped region defined by two pairs of oppositely signed half integer disclinations Scale bars, 0 5 μm

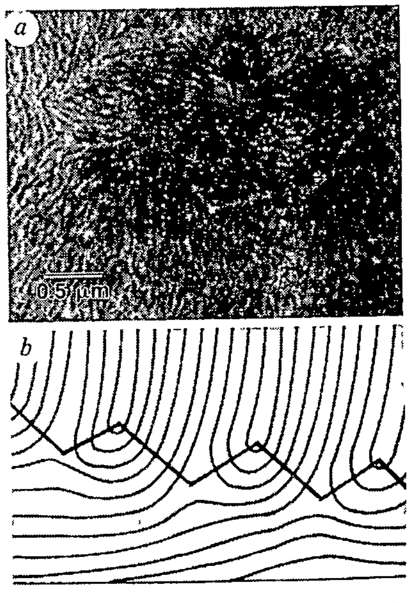

Fig 4 *a*, TEM image of region of approximately uniform orientation defined by walls of alternating positive and negative disclinations and *b*, schematic of a disclination wall (ref 1) Scale bar, 0 5 μm

uniform orientation are enclosed by disclinations where continuous rotation of the molecular director occurs about an axis parallel to the disclination lines (Neel walls in the language of magnetism) Except in the vicinity of the disclination cores, the field of molecular director trajectories is both continuous and translationally parallel

Rapid reduction of nitrogen oxides in exhaust gas streams

R. A Perry & D. L. Siebers

Combustion Research Facility, Sandia National Laboratories,
Livermore, California 94550, USA

Nitrogen oxides (NO_x) play a major role in the formation of photochemical smog and in acid rain production[1] Some progress has been made in reducing NO_x emissions through the use of combustion and exhaust control schemes, including three-way catalyst, staged combustion, and ammonia injection. Nevertheless, estimates indicate that the production of nitrogen oxides will continue to increase until the end of the century and beyond, if current trends continue[2] We describe here a new chemical process capable of completely removing NO_x from the products of combustion The effectiveness of this process is established in flow tube experiments. Further, we demonstrate the practical feasibility of this method by eliminating NO_x from a portion of the exhaust from a single-cylinder diesel engine. Based on these results we conclude that this process for rapid reduction of nitrogen oxides could play a major role in controlling NO_x emissions from most combustion devices.

Nitrogen oxide formation in combustion has received much attention[3-7] The recognition[4] that ammonia can be used to reduce nitric oxide in exhaust gases led to major efforts to characterize reactions important in the Thermal $DeNO_x$ process The mechanisms and models that resulted have greatly improved understanding of nitrogen chemistry in combustion For example, this research led to the prediction of nitric oxide concentrations in ammonia injection schemes[5,7] and in general nitrogen chemistry in combustion[6,7] Experimental efforts have continued to increase our understanding of the radical species important in the conversion of fuel-bound nitrogen to N_2 and NO during combustion Perry[8] studied reactions of the NCO radical with combustion species NCO radicals formed from the photolysis of isocyanic acid (HNCO) react very rapidly with nitric oxide, suggesting[8] that this reaction might be important in nitrous oxide formation in combustion These observations, combined with previous insights into nitrogen chemistry, led to a new scheme for NO_x reduction[9]

The proposed nitrogen oxide reduction scheme is based on the addition of isocyanic acid to an exhaust stream containing NO_x Isocyanic acid is formed from the decomposition of cyanuric acid (a nontoxic, commercially available compound) when cyanuric acid is heated above approximately 330 °C

$$(HOCN)_3 \xrightarrow{\Delta} 3HNCO$$

When HNCO is mixed with an exhaust gas stream at temperatures $\geq$400 °C, a series of reactions occur that result in the loss of HNCO and NO Using a long-pass optical cell with Fourier transform infrared (FTIR) detection, carbon monoxide, carbon dioxide, water, and nitrogen (by inference) are observed as products Table I shows results obtained in initial flow reactor experiments to study the overall chemistry of the proposed scheme This process has been used to remove more than 99% of the nitric oxide emissions in simulated and real exhaust gas streams containing from 250-3,000 p p m by volume of NO

The flow reactor was a 3 8 cm diameter stainless steel tube 1 m long, enclosed in a furnace The simulated exhaust gas was sampled with a 6 4 mm quartz probe, the position of the probe tip was varied over a range of 70 cm by the use of a stepping motor The flow rates of the gases used (Ar/NO/HNCO) were controlled and measured with calibrated mass-flow controllers Residence times in the flow reactor were determined from the equation $t = Ad/V$ where t is time, V is flow rate, A is the cross sectional area of the tube, and d is the distance from the point of mixing The temperature of the tube was measured using chromel/alumel thermocouples, and the pressure in the tube was measured using a capacitance manometer

Although the initiation chemistry is uncertain, some observations regarding the overall chemical process can be made from the flow-tube experiments The most prominent feature of the results (Table 1) is the decrease in NO and HNCO concentration and the formation of CO and CO_2 It is evident from the data that the process occurs on a 1 1 molar basis

Table 1 Flow data obtained from stainless steel flow reactor using simulated exhaust gases (Ar/NO/HNCO mixture)

* $[HNCO]_i$ is the initial HNCO concentrations calculated assuming carbon mass balance from the equation $[HNCO]_i = [HNCO]_f + [CO_2] + [CO]$
† [NO] determined by NO_x chemiluminescent analyser
‡ [CO], $[CO_2]$ and [HNCO] measured using absorption at selected lines precalibrated with known concentrations of CO, CO_2, HNCO

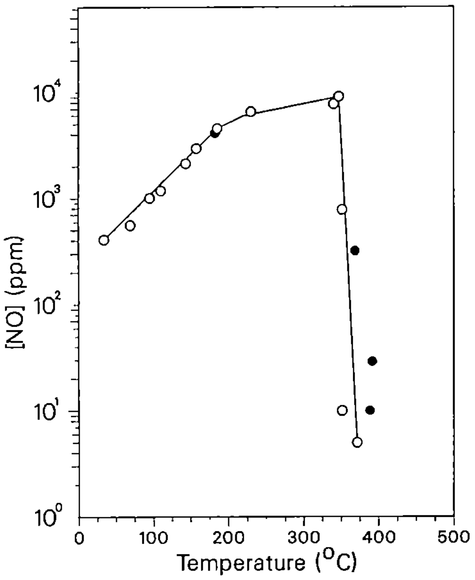

Fig 1 Plot of NO concentration (p p m) in treated portion (1 0 1 min^{-1}) of diesel engine exhaust gas versus cyanuric acid bed temperature (°C) The diesel engine was operated at medium load (overall equivalence ratio of 0 5) and 1,800 r p m Instrumentation sensitivity is limited to ~5 p p m Data were obtained on successive days, with solid circles taken initially and open circles obtained in separate experiments

The following possible reaction scheme, when combined with previously developed models[5–7], may explain these experimental results

$$\begin{aligned} HNCO &\xrightarrow{\Delta} NH+CO \\ NH+NO &\rightarrow H+N_2O \\ H+HNCO &\rightarrow NH_2+CO \\ OH+CO &\rightarrow H+CO_2 \\ NH_2+NO &\rightarrow N_2H+OH \\ &\rightarrow N_2+H_2O \\ N_2H &\rightarrow N_2+H \end{aligned}$$

This reaction scheme implies that, following initiation, the sequence through N_2H produces a growth of one hydrogen atom per cycle to sustain the chain One important aspect of the chemistry of our proposed method is the absence of the need for controlled amounts of oxygen, suggesting that it could be readily implemented as a control process, if the presence of oxygen does not greatly change the mechanism

To test the effect of excess oxygen on the process, and to develop a technology for exhaust conditions that are presently untreatable by existing technologies, such as 3-way catalyst and ammonia injection, we used the proposed method to reduce the nitrogen oxides in a portion of a diesel engine exhaust gas stream The experiments used a single cylinder, 7 2 horse power Onan diesel engine The engine was operated at a medium load condition (an overall equivalence ratio of 0 5) and an engine speed of 1800 r p m A continuous sample of unfiltered exhaust gas was drawn at a rate of 1 l min^{-1} and passed over cyanuric acid in a 14 6 cm long by 4 72 cm diameter stainless steel tube with a volume of 256 cm^3 (the cyanuric acid bed) The sample then flowed through a 17 8 cm long by 2 2 cm diameter tube packed with two sizes of stainless steel spheres, diameter 0 55 cm and 0 64 cm (the packed bed), which had an open volume of 31 cm^3 and a total surface area including steel spheres of 1,630 cm^2 The packed bed was used to test the effect of surface-to-volume ratio and residence times on the chemistry Finally, the exhaust gas flowed through a NO_x chemiluminescence analyser Samples also were taken of the treated and untreated exhaust gas for FTIR analysis

Figure 1 shows the results of the diesel engine experiments The NO concentration measured in the treated exhaust gas is plotted as a function of the cyanuric acid bed temperature For cyanuric acid bed temperatures above 360 °C the NO_x was essentially eliminated These results were insensitive to packed bed temperatures between 450 °C and 900 °C, provided that the cyanuric acid bed temperature was greater than 360 °C At lower acid bed temperatures, nitric oxide levels in excess of that produced by the diesel engine (410 p p m) were observed (Fig 1) Surface interactions of HNCO with oxygen are believed to be important in this effect, and suggest the need to minimize the surface area in designing a practical device Experiments using gaseous HNCO injection in oxidizing environments, which show that NO-reduction takes place efficiently in the presence of excess oxygen, will be reported with related results in detail

In summary, we have discovered a chemical means of removal of NO_x from the products of combustion or industrial emissions, and we have demonstrated its feasibility on a portion of the exhaust from a diesel engine This process has important implications for a wide spectrum of energy conversion technologies and for industrial applications that presently produce NO_x as exhaust byproducts

A magmatic heat pump

S. A. Morse

Department of Geology and Geography,
University of Massachusetts, Amherst, Massachusetts 01003, USA

The structures of igneous cumulates can provide valuable clues to inaccessible magmatic processes. Many mafic layers in the Rhum Intrusion have 'finger structures'[1–3] that protrude into the overlying felsic rocks. These structures are attributable to melting of the overlying olivine–feldspar rocks by hot mafic magma emplaced as sills[4]. The bases of mafic layers contain smooth-bottomed olivine cumulates. Here I show that the heat needed to melt the roof of the layer is carried by rapidly rising light solute released by growth of basal olivine crystals that were deposited by two phase-convection. Compositional convection therefore drives a heat pump transferring heat of fusion from remote growing crystals to those that are melting. This action contrasts with cooling under a refractory roof, which is conduction-limited. The heat pumping principle shows why ultramafic magmas may melt their roofs whereas felsic magmas tend to form upper border zones.

Details of the crystallization sequence in the finger structures reported at Rhum have led to the realization that the mafic layers are pene-contemporaneous sills whose presence has caused melt-corrosion of the overlying rock[4] Details are clarified in ref 4, but the features central to the present discussion may be summarized as follows Finger structures occur only in troctolite (olivine-plagioclase rock, often called allivalite) overlying mafic layers rich in olivine cumulate They are interpreted as melting features because the host rock fabric is continuous across the fingers, which therefore represent passive removal of felsic material and subsequent crystallization of mafic material The crystallization sequence olivine-pyroxene in the fingers shows that the mafic material was supercooled when it finally solidified in the finger spaces[4] The initial mafic magma was hot enough to dissolve the troctolite, so it was in the olivine field, not yet co-saturated with plagioclase feldspar and certainly not with pyroxene The mafic layers have thicknesses commonly in the range 5–100 cm

Melt features seem to be absent at the bases of the mafic layers (There are load structures into crystal mushes of troctolite[3], but these do not require melting at the local site) The magma layers were emplaced into essentially solid troctolite, mineral compositions above and below the layers are similar, typically $Fo_{84\pm2}$ in olivine, for example[5] The initial state immediately after injection was therefore that of a hot, essentially isothermal magma layer sandwiched between cooler felsic rocks Melting should have begun immediately at both boundaries Instead, there is abundant evidence of melting at the upper boundary, but no firm evidence of melting at the lower

The first obvious difference between the top and bottom boundaries is the presence of a basal olivine cumulate layer below (Fig 1) This crystal layer can act as a thermal blanket and as a physical barrier to percolation of hot, dense liquid Three kinds of convection are relevant two-phase, compositional, and thermal The rapid deposition of olivine crystals is promoted by two-phase convection[6,7] of crystal-liquid suspensions from the cooler top of the mafic magma layer (This result differs from those based on calculations of the Rayleigh number that suggest enduring turbulence and suspension instead[8] However, the latter were reached without consideration of two-phase convection An alternative route to a quite different set of Rayleigh numbers has been suggested by Marsh[9]) Growth of olivine releases a light solute[10] that convects freely upward[11], it also locks the local temperature onto a thermal maximum called a 'latent heat hump'[12] The resulting compositional convection is an important agent in causing solidification of the porous olivine cumulate[10,11,13,14] The rapid formation of such a solid caprock is required to prevent percolation of the magma to the underlying layer The entire convective cycle is driven by absorption of heat at the roof of the mafic magma layer, which, in turn, drives two-phase convection , which carries downwards the heat sink needed to induce growth at the floor and thereby to induce compositional convection

Thermal convection runs in the same direction as compositional convection but is less important A useful measure of the relative potentials of compositional verus thermal convection is provided by the density ratio $R_\rho = \beta\Delta S/\alpha\Delta T$, where $\beta\Delta S$ is a compositional expansion times a concentration change and $\alpha\Delta T$ is a thermal expansion times a temperature change The density ratio has been evaluated for the growth of cumulates[15], and found to lie between six and 10^6, with the larger values more common Such large values show that the compositional contribution to buoyancy greatly exceeds the thermal contribution, and hence that the convection is dominantly compositional

Corrosion of the roof rocks is extensive (Fig 1) The latent heat released by the crystallization of 1 g of olivine can melt 2 g of troctolite[16] Accounting for the lower density of the troctolite, a given volume of dunite can account for removal of ~2 5 times as much troctolite The olivine present in the rest of the mafic layer, along with the basal olivine, can easily account for the missing troctolite in terms of latent heat The thermal budget of a crystallizing magma sheet melting its roof was addressed by Irvine[17] Applying the relations of his Fig 14 to the present case, it can be judged that about twice as much cumulate can form when the heat evolved is absorbed by melting at the roof, compared to conduction alone through the roof

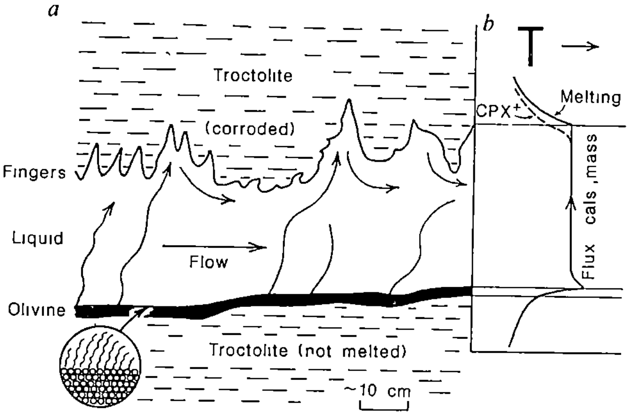

Fig 1 *a*, Rhum finger structures above a mafic layer with an olivine cumulate base (black), after a photograph (Fig 163 of ref 2) The cotectic felsic+mafic material (troctolite) below the mafic layer shows no evidence of melting, in contrast to that in the base of the overlying layer This asymmetry is accounted for by strong compositional convection of light rejected solute away from the growing basal olivine layer (shown by the magnified view in the lower circle) This convection pumps the heat of fusion through the mafic liquid to melt the overlying troctolite, where heat is absorbed The thermal relations are shown schematically in *b* When the convectional stirring becomes weak, supercooling within the fingers allows metastable growth of pyroxene (dashed curve labelled CPX⁺) The thermal maximum (latent-heat pump) at the top of the olivine cumulate arises from the local maximum of latent heat released[12] A small supercooling of the average magma is assumed, to allow for nucleation of olivine The mafic magma may be 100 °C or so hotter than the troctolite

It is proposed, therefore, that recrystallization of olivine in the mafic magma released most of the heat needed to dissolve the roof rocks Rising streams of rejected solute (Fig 1) will stir the magma layer and carry heat of crystallization away from the growing interface[12] Complementary two-phase plumes of olivine-seeded magma will carry supercooling downwards to allow growth of the basal cumulate, which is aided by conduction through the floor The resulting temperature profile is portrayed in Fig 1 The latent-heat hump occurs where the most olivine is growing, near the cumulate interface The average magma temperature is shown as supercooled to allow for the nucleation and growth of olivine and eventual metastable crystallization of pyroxene Physical stirring by the rising rejected solute keeps the liquid essentially isothermal The ambient temperature at the roof is high enough to melt the roof rocks The compositional convection therefore acts as a heat pump from the crystallizing base of the layer to the melting roof The melted material is flushed away from the propagating fingers and dissolved in the feldspar-undersaturated mafic magma The process must be rapid to avoid heating the walls of the fingers excessively, because they ultimately chill the liquid into the metastable pyroxene field[4] The chilling presumably occurs when the heat-pumping process has died down below some critical threshold velocity

The magmatic heat pump is similar to a classical isothermal heat pipe driven by the counterflow of two phases such as water and steam The magma layer is also sensibly isothermal, but here the counterflow consists of a two-phase flow originating at one interface balanced by a single-phase, density contrast flow originating at the other The pump and pipe are similar in transferring latent heat from one boundary to another

Melting on a much grander scale evidently occurred at the Muskox Intrusion in Canada, where the roof rocks of the intrusion were extensively melted[17] during the crystallization of the olivine-rich cumulates It seems that heat pumping by compositional convection occurred here on a massive scale. The paired heat source (olivine cumulate) and sink (fusible roof rocks) were both present, and compositional convection must have operated strongly. The pumping action could be damped but not erased by any convective stirring, because compositional convection will act over at least part of the distance of travel. If paired two-phase and compositional convective streamers or plumes dominated the convective flow pattern, heat pumping may have acted directly from floor to roof.

By contrast, felsic cumulates have a dense rejected solute[10] that cannot transport heat upwards through the overlying magma. Roof melting would therefore not be expected in felsic intrusions and frozen upper border zones are observed at such felsic intrusions as Skaergaard[15] and Kiglapait[10]. The rollover point between dense and buoyant rejected solute occurs, in mafic magma series, approximately at magnetite saturation[15], hence magnetite-bearing calc-alkaline magmas can more readily melt their roofs by heat pumping from cumulates than tholeiitic and more reduced magmas. This principle accords with the common impression that calc-alkaline series magmas tend to show more contamination effects than Fenner-trend magmas. The extended calc-alkaline effect is much weaker than the effect seen in very mafic magmas, because the latent heat of fusion of magnetite is less than that of magnesian olivine and magnetite generally crystallizes in company with feldspar, so that the bulk contributions of both latent heat and buoyant solute are small compared with magmas crystallizing olivine.

Although roof melting is not anticipated for felsic intrusions, the drainage of hot, dense solute from felsic roof cumulates implies that floor melting might occur by heat pumping. This could be the case for certain anorthosites and other felsic cumulates early in their history. However, this process is self-limiting because it produces an upper thermal blanket of roof cumulates through which conduction will have to occur for the magma to crystallize. By contrast, heat pumping with roof melting continually exposes cooler material to the magma, thus maximizes cooling and crystallization rates[17].

Heat pumping by compositional convection may account for roof melting on scales ranging from individual layers at Rhum to whole intrusions emplaced into fusible crust. Pumping is most efficient when the basal cumulate is ultramafic and the roof is readily melted. This combination may occur most commonly for early olivine cumulates, but might also occur for later magnetite cumulates. The crystallization of magnetite in company with other mafic crystals and feldspar renders most calc-alkaline cumulates weakly capable of pumping. Inverted heat pumps from felsic roof rocks are inherently self-limiting because they impose an insulting cumulate in the path of heat removal to the Earth's surface.

Formaldehyde oxime leaching of metals from deep-sea manganese nodules and other ores

R. Derie

Department of Ore Dressing, Université Libre de Bruxelles,
50 Avenue Roosevelt, B-1050 Brussels, Belgium

Formaldehyde oxime, $CH_2{=}NOH$, has for a long time been recognized as a sensitive colorimetric reagent for manganese, copper and metals of the iron group. In alkaline medium, the oxime dissociates, forming the $CH_2{=}NO^-$ anion which bonds to multivalent metals, giving complexes of the general formula $M(CH_2NO)_6^{(6-n)-}$, where n is the oxidation state of the metal[1,2]. Here I report the results of experiments which show that aqueous formaldehyde oxime constitutes a new and effective leaching agent for several types of ores, such as pyrolusite, malachite, heterogenite and deep-sea manganese nodules. The reagent seems particularly attractive for nodules, as the leaching is rapid, in acid as well as in neutral and/or alkaline media, and at ambient and lower temperatures. Manganese nodules constitute an important potential source of nickel and especially cobalt: the amount of cobalt recoverable from the north-west equatorial Pacific alone is estimated[5] to be 4×10^6 tonne—of the same order as the world total land-based reserves.

The formaldehyde oxime solutions were prepared by mixing solid hydroxylamine hydrochloride with an equimolar amount of a 38 wt% aqueous solution of formaldehyde. The reaction is immediate, yielding a concentrated solution of formaldehyde oxime, which is then diluted and brought to the desired *p*H by addition of ammonia or sodium hydroxide.

The exact origin of the nodules, collected during the 1974–78 campaign of Ocean Mining Associates, is unknown, but their composition (Mn 28.9, Fe 5.02, Ni 1.29, Cu 1.04, Co 0.24, Zn 0.13, Mo 0.065, V 0.051 wt% on dry basis) is very similar to that of the nodules from the Clarion-Clipperton zone (eastern Pacific Ocean)[2]. The X-ray diffraction spectrum (Fe Kα line) consisted only of the four major, broadened, lines of todorokite, plus the main quartz line.

Other materials selected for the leaching experiments were a phosphorus-rich manganese ore (Mn 31.6, Ca 13.0, P 0.25 wt%) from Raouisse (Vanuatu) in which we identified pyrolusite (β-MnO_2) and calcite, and a complex Zairian copper-cobalt ore, consisting mainly of badly crystallized heterogenite (CoOOH) and malachite, together with some muscovite and diaspore.

All these materials were ground to <106 μm. The dissolution experiments were carried out in a thermostated vessel, fitted with a simple magnetic stirrer. At intervals, samples were taken from the reaction medium, filtered and then analysed by atomic absorption or atomic emission (DCP) spectrophotometry.

Pyrolusite (as well as laboratory-grade MnO_2) dissolves easily in formaldehyde oxime solutions. From *p*H 5-11 (experiments beyond this limit were avoided as the oxime is sensitive to oxidation in alkaline medium) a brownish-red coloration appears instantaneously, evidence of the formation of the $Mn(CH_2NO)_6^{2-}$ anion. The reaction is rapid: for example, at 20 °C and pH 9.8, with 1.5 g ore in 300 ml 1M formaldehyde oxime, >90% of the Mn passed into solution after 5 min, the leaching being complete after ~10 min. Under these conditions, the gangue minerals (calcite and apatite were identified in the residue) were left practically unaltered.

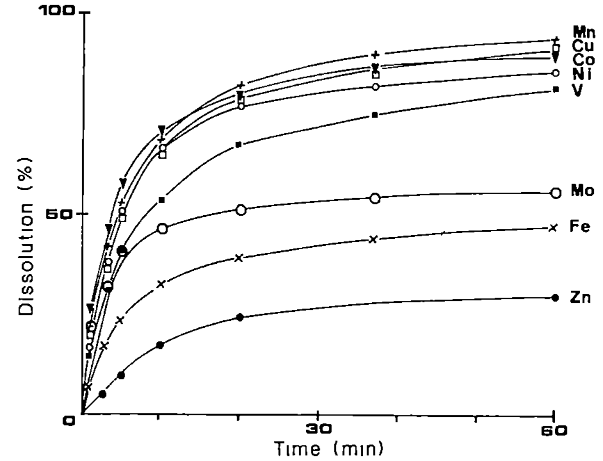

Fig. 1 The extraction of various elements from eastern Pacific manganese nodules (for conditions see text).

Separate dissolution experiments made under the same conditions as above have shown that among calcite, dolomite, magnesite, fluoroapatite and goethite, which are main gangue minerals of manganese ores, only calcite dissolved to a significant extent (25 mg Ca per litre solution after 60 min).

The quantity of manganese dioxide that can be dissolved in formaldehyde oxime solutions corresponds roughly to the stoichiometry of the reaction, that is, the formation of the hexacoordinated complex. Thus 1 litre of 1 M formaldehyde oxime solution dissolves 0.14 mol MnO_2 (12 g) at 20 °C and *p*H 9.8.

When the dissolution is done in an acidic medium (*p*H <5), the oxime is oxidized by MnO_2, and colourless solutions of Mn(II) are produced.

The powdered nodules dissolve even faster than pyrolusite in formaldehyde oxime; the solutions are also very dark. To slow the reaction rate the dissolution experiments were done in an ice bath.

Figure 1 shows an example of the results. The conditions were: temperature 0 °C, *p*H 7.5, 1.5 g nodule in 500 ml 0.5 M formaldehyde oxime. The percentage of every element passing into solution is represented as a function of time.

Other experiments were made under different *p*H conditions: as a rule, the dissolution paths of Mn, Ni, Cu and Co are always very similar (these elements are closely associated in the todorokite structure) and are not influenced by the alkalinity of the medium, in the *p*H range ~6–11.

The amount of iron dissolved never exceeded 70% of the iron content of the nodules, even if the leaching experiment was prolonged to 24 h at ordinary temperature. The mineralogical support of this insoluble iron was not identified, as only quartz, labradorite—a felspar-type mineral—and traces of a 7-Å clay mineral were identified by X-ray diffraction in the dissolution residue.

The dissolution behaviour of the other valuable elements of the nodules is more or less pH-dependent.

Table 1 Dissolution kinetics of copper and cobalt from a complex heterogenite—malachite ore (for conditions see text)

Time (min)	Co dissolved, wt %	Cu dissolved, wt %
1	12	5
3	27	9
5	43	12
10	64	16
20	70	21
30	77	27
75	94	34
120	98	40

By changing the experimental conditions, and particularly by raising the nodule: oxime ratio, we leached most (75–95%) of the nickel, copper and cobalt, leaving 45% of the manganese and >99% of the iron in the solid residue. These results could have a long-term economic interest, and will be discussed later (R.D., in preparation).

The third substance studied was the complex copper–cobalt ore. We observed that heterogenite always dissolves faster than malachite, and to ensure complete extraction of copper in a reasonable time it is necessary to operate at ≥35 °C. We did not succeed in leaching copper or cobalt selectively. As an example, table 1 gives the percentages of these elements dissolved, as a function of time at 20 °C and *p*H 7.0, with 1.5 g ore in 500 ml 0.5 M formaldehyde oxime.

Because most of the oxide, hydroxide and carbonate ores of copper and cobalt are easily leached by ammonia and/or mineral acids, economic interest in leaching by formaldehyde oxime seems unlikely. It is nevertheless remarkable that this leaching may be done in a neutral medium.

Little is known about the formation constants of metal–formaldehyde-oxime complexes. The only published data are those of Bečka and Jokl[4]; the values are high (log $K_{\text{form}} = 7.5$, 9.8, 17.3, and 18.9 respectively for the Cu (II), Mn (IV), Fe (III) and Ni (IV) complexes), indicating a stability much greater than, say, that of the ammine complexes of Cu and Ni. This alone cannot account, however, for the reactivity of formaldehyde oxime solutions towards the particular minerals studied here, as indicated by the fact that manganese dioxide is easily attacked by the oxime, but not iron oxyhydroxide (goethite), whereas the stability of the Fe (III) complex is seven orders of magnitude greater than that of the Mn (IV) complex.

The imperfections in the crystal lattices of the minerals must play a prominent role in their reactivity; this is probably also true for deep-sea manganese nodules, which have a poorly crystallized structure.

This reaction between nodules and aqueous formaldehyde oxime seems promising, as a rapid and more or less selective extraction of the valuable elements is attainable, even at low temperature. So far, however, only the leaching operation has been studied in our laboratory, and attention will be given to the recovery of the dissolved metals and the recycling of the oxime.

I thank Professor George Panou, Director of the Department, for fruitful discussions.

Homoeobox gene expression in mouse embryos varies with position by the primitive streak stage

Stephen J. Gaunt, J. Ross Miller,

Pattern formation in animal development requires that genes be expressed differentially according to position in the sheets of cells that make up the early embryo. The homoeobox-containing genes of *Drosophila* are control genes active both in the establishment of a segmentation pattern[1,2] and in the specification of segment identity[2,3]. *In situ* hybridization experiments[4–6] confirm that these genes are expressed in a segmentally-restricted manner and that their expression presages morphological differentiation of segmental structures. Homoeobox genes have recently been isolated from the mouse[7–12] and have been shown to be expressed during mouse development[9–13]. Using *in situ* hybridization, we show here that expression of the mouse homoeobox gene *Mo-10* (ref. 7) is spatially restricted in the developing embryo and that localization of expression is already evident within the germ layers before their morphological differentiation. These findings support the suggestion[14] that the homoeobox genes of mammals, like those of *Drosophila*, may be important in pattern formation.

To examine expression of the *Mo-10* gene (also known as *Hox*-1, ref 9), the 660-bp *Hin*dIII-*Eco*RI fragment containing the homoeobox was subcloned into pSP65 and used to produce high specific activity radioactive RNA probes complementary to *Mo-10* messenger RNA (Fig. 1). Two separate probes were made. Probe 1 contains 144 nucleotides from the homoeobox and ~70 nucleotides of additional 3′ sequence. Probe 2 resembles probe 1, but includes the whole of the homoeobox plus ~400 nucleotides of 5′ sequence. Both probes gave similar results in the *in situ* hybridization experiments.

The $9\frac{1}{2}$ day-old embryo was the most advanced stage to be examined. By this age most of the organ systems of the body are already laid down (Fig. 2*a*). The most intense labelling is seen in the nervous system (Fig. 2*b*). Anterior parts of the neural tube, developing at this stage as the forebrain and midbrain regions are not labelled above background, but intense labelling begins posterior to a point in the hindbrain region just anterior to the otic vesicle, at the level of the second (hyoid) visceral arch. The whole length of the neural tube posterior to this point is labelled, but the concentration of grains declines in more posterior regions. We examined the boundary between labelled and unlabelled parts by phase contrast optics, but found no corresponding morphological change in the neural tissue. At this stage of development metameric segmentation of the hindbrain is apparent in its serial constrictions to form neuromeres. The boundary between labelled and unlabelled neural tissue coincides with the boundary between two neuromeres.

The pattern of labelling observed in non-neural tissue of the $9\frac{1}{2}$ d embryo was less remarkable. Generally, labelling was above background in most posterior mesodermal structures, such as the mesonephric kidney and the somite blocks (not shown), but the labelling was weak compared to that of the nervous system. Mesoderm-derived tissues in the head (Fig. 2*b*), the heart, the liver, the gut, and the appendages all showed only background labelling.

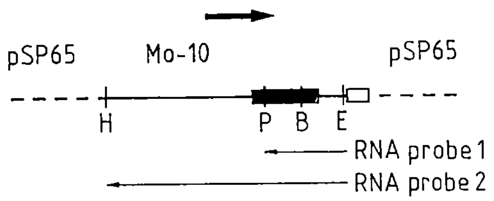

Fig. 1 Use of a pSP65 plasmid[15] containing the *Mo*-10 homoeobox to prepare radioactive RNA probes for *in situ* hybridization and Northern blotting. H, *Hin*dIII, P, *Pvu*II, B, *Bgl*II, E, *Eco*RI. The homoeobox and the SP6 promotor are shown as filled and open boxes respectively. The normal direction of transcription of the *Mo*-10 DNA is from left to right (bold arrow) based upon the conserved open reading frame[7] and homology with the known direction of transcription of other homoeobox genes[10–12].

Methods. To construct the plasmid, the *Hin*dIII-*Eco*RI fragment containing the homoeobox was obtained from a cosmid clone of mouse genomic DNA[16]. The nucleotide sequence (not shown) of this homoeobox is more then 99% homologous to the published sequence[7]. Radioactive RNA probes complementary to putative *Mo*-10 mRNA were prepared after digestion of plasmid DNA with either *Pvu*II (probe 1) or *Hin*dIII (probe 2), followed by *in vitro* transcription using SPS6 RNA polymerase (Promega Biotec). Labelled ribonucleotide triphosphates used were: for *in situ* hybridization, ^{3}H-UTP and ^{3}H-CTP (Amersham, 20 μCi of each, carrier-free, per 20 μl reaction), for Northern blotting, ^{32}P-UTP (Amersham, 50 μCi, 0.2 μg per 20 μl reaction). Final specific activities were about 9×10^7 d.p.m. per μg for ^{3}H-labelled probes and 2×10^8 d.p.m. per μg for ^{32}P-labelled probes. Probes for *in situ* hybridization were subjected to limited alkaline hydrolysis as described[17] for either 45 min (probe 1) or 90 min (probe 2). Probes were then checked by gel electrophoresis to ensure that the bulk of the RNA was reduced to 50–150 nucleotides. A control probe of opposite sense to the probes described above was prepared after subcloning the *Hin*dIII-*Eco*RI fragment of *Mo*-10 DNA into pGEM-4 (Promega Biotec), then using T7 RNA polymerase in the transcription reaction. This probe, hydrolysed as above, did not produce specific labelling when used in the *in situ* hybridization experiments.

At $7\frac{1}{2}$ d of gestation, the cells that will form the mouse are arranged as the three germ layers: ectoderm, mesoderm and endoderm (Fig. 3*a*). But in the posterior region (the site of the primitive streak) ectoderm and mesoderm layers remain unseparated. By $7\frac{3}{4}$ d (Fig. 3*c*), anterior ectoderm in the region of the head fold has become thickened and elevated, presaging the formation of the brain. *In situ* hybridization experiments on embryos at these stages show that labelling is restricted to posterior regions, including the primitive streak (Fig. 3*b*) and adjacent regions of ectoderm and mesoderm (Fig. 3*d*). The anteroposterior boundary between unlabelled and labelled regions is not sharply defined at these stages of development. From examination of twelve $7\frac{1}{2}$ d to $7\frac{3}{4}$ d embryos cut in sagittal section, it was found that labelling varied from about one-third to two-thirds of the length of the embryo, with older embryos tending to show the greater extent of labelling. The extraembryonic tissues at these stages showed only background labelling.

In Northern blot analysis of poly(A)$^+$ RNA extracted from $9\frac{1}{2}$ d and $10\frac{1}{2}$ d whole mouse embryos, probe 1 hybridized with two distinct transcripts of 4 kilobases (kb) and 1.7 kb (Fig. 4). The bands were detected after washing the filter under highly stringent conditions, suggesting that both transcripts are products of the *Mo-10* gene.

The *in situ* hybridization results are consistent with the hypothesis[14] that the homoeobox genes of mammals, like those of *Drosophila*, may be important in the specification of body pattern. The two main observations which suggest such a role for the *Mo-10* gene are, first, that its expression in embryos is spatially restricted in tissues that appear uniform in cell composition on the basis of morphology alone and second, that spatial restriction in expression is evident very early in development, before any observable signs that the body pattern has already been laid down. Since precise fate maps are not available for mouse embryos, it is not possible to conclude that the labelled

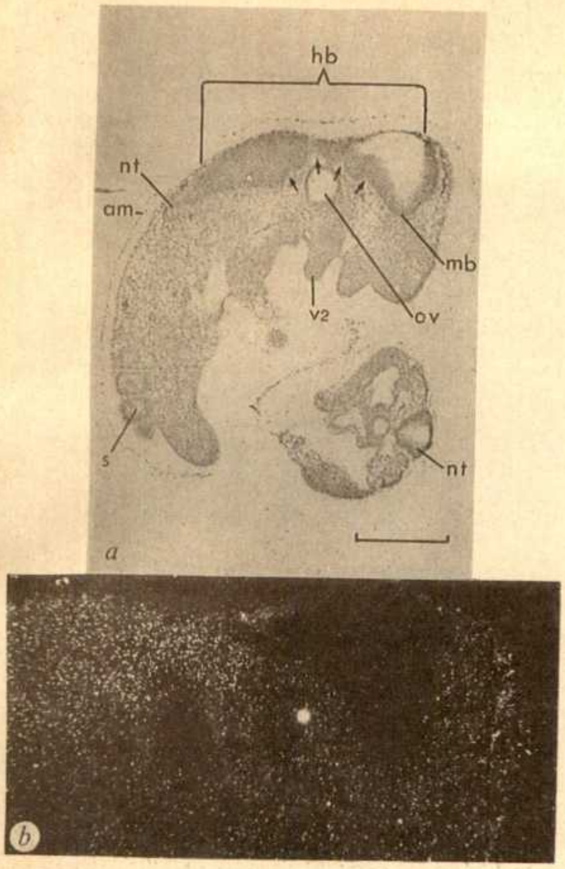

Fig. 2 Localization of *Mo*-10 transcripts, using probe 2 (Fig. 1), by *in situ* hybridization on sections of the $9\frac{1}{2}$ d mouse embryo. *a*, Embryo cut in parasaggital section, under bright-field illumination. hb, hindbrain; mb, midbrain; nt, neural tube; ov, otic vesicle; v2, second visceral arch; s, somite; am, amnion; arrows, constrictions between neuromeres. Scale bar, 0.5 mm. *b*, Silver grains in the head region of the same section, viewed under dark-field illumination. The most intense labelling was detected in the nervous system, but labelling was not seen in anterior regions of the brain. The boundary between labelled and unlabelled neural tissue was located in the hindbrain at the junction of two neuromeres.

Methods. Embryos were obtained from natural matings between F_1 (CBA × C57Bl/6) mice. The morning that the copulation plug was found in the vagina was designated day $\frac{1}{2}$ of pregnancy. After dissection from the uterus into phosphate buffered saline, the embryos were fixed in Bouins fluid for 24 h at 4 °C. They were then dehydrated in ethanol, cleared in xylene, and embedded in paraffin wax (m.p. 56 °C). Sections (10 μm thick) were mounted on poly-L-lysine treated glass microscope slides, dried at 37 °C for 4 h, de-waxed in xylene, rehydrated in decreasing ethanol concentrations and digested with proteinase K as described[17]. Treatment with acetic anhydride and the conditions of hybridization, digestion with RNAase A and washing were as described[18]. After the final wash, sections were immersed in 0.3 M ammonium acetate in 95% ethanol and allowed to dry in air. Slides were dipped at 50 °C in Ilford L4 emulsion diluted 1 : 2 with water, allowed to dry and stored at 4 °C. After an exposure time of three weeks, the autoradiograms were developed in Kodak D19 developer for 3 min at 20 °C. The tissue sections were then stained in Giemsa, dehydrated in ethanol and mounted under coverslips in DPX mountant.

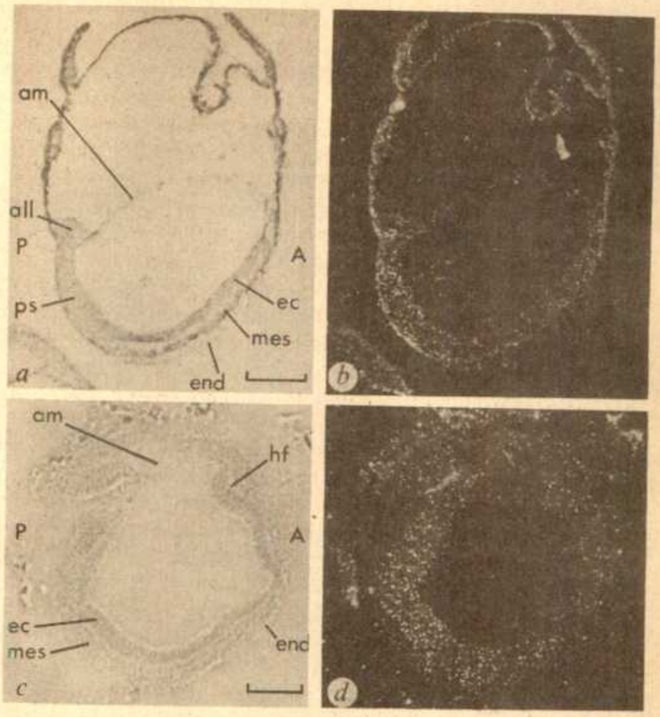

Fig. 3 *In situ* hybridization to detect *Mo*-10 transcripts in sections of primitive streak stage mouse embryos. *a*, *b*, $7\frac{1}{2}$d embryo in sagittal section examined with probe 2; *c*, *d*, $7\frac{3}{4}$ d embryo in parasagittal section, probe 1. *a* and *c* show sections by bright-field and phase contrast illumination respectively. A, anterior; P, posterior; ps, primitive streak; ec, ectoderm; mes, mesoderm; end, endoderm; am, amnion; all, allantois: hf, head fold. Scale bars, 0.1 mm. *b* and *d* show the sections by dark-field illumination. Labelling was restricted to the posterior regions of the embryonic tissue, including the primitive streak (*b*), ectoderm and mesoderm (*d*). The bright border seen at some positions along the edge of the embryonic and extraembryonic tissues in *b* is not due to silver grains, but to a light scattering effect by material which was often present at this stage. Methods were as for Fig. 2.

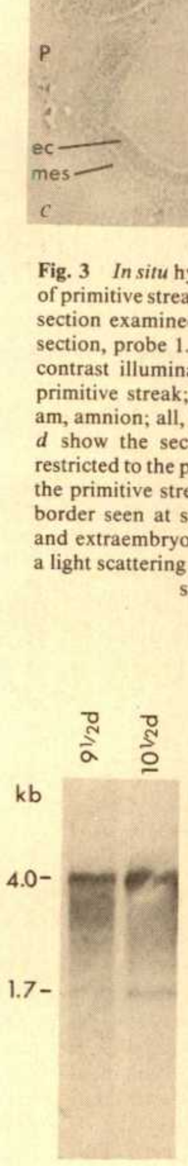

Fig. 4 Northern blot hybridization of *Mo*-10 probe 1 (Fig. 1) to poly(A)$^+$ RNA isolated from whole mouse embryos of $9\frac{1}{2}$ and $10\frac{1}{2}$ d gestation.

Methods. RNA was prepared as described[19]. About 5 μg of each poly (A)$^+$ RNA sample was separated by electrophoresis through a formaldehyde-agarose gel. RNA was then blotted on to Gene Screen Plus. The filter was prehybridized for 2 h at 60 °C in 1 M NaCl, 50 mM Tris HCl *p*H 8.0, 1% SDS, with 100 μg ml^{-1} *Escherichia coli* transfer RNA and 10 μg per ml sonicated salmon sperm DNA. Hybridization with ^{32}P-labelled probe 1 was carried out overnight under the same conditions but with 10% dextran sulphate added. The concentration of probe was about 2 ng ml^{-1}. The filter was washed twice in 2 × SSC, 1% SDS at 65 °C for 20 min, then once in 0.1 × SSC, 1% SDS at 65 °C for 20 min before autoradiography.

ectoderm tissue seen in the $7\frac{1}{2}$ d embryo would normally have given rise exactly to the labelled neural tissue seen at $9\frac{1}{2}$ d. Before drawing such a conclusion it would be necessary to examine several intermediate stages since the primitive streak region is one of considerable cell proliferation and migration.

It is possible that the spatial restriction of gene expression that we have described is not primarily concerned with pattern formation, but instead reflects some other developmental difference between the trunk and head regions of the mouse. However, some observations recently described for the mouse homoeobox gene *Mo-EA*[1,12] suggest further parallels between patterns of expression of homoeobox genes in *Drosophila* and in mice. Awgulewitsch *et al.*[12] used *in situ* hybridization to localize *Mo-EA* transcripts in the nervous system of newborn mice. Labelling was absent in anterior regions of the nervous system but began at about mid-cervical region. Labelling was most concentrated at this point, becoming less intense in more posterior regions of the spinal cord. Thus, *Mo-EA* transcripts, like *Mo-10* transcripts, are detected only posterior to a discrete boundary in the nervous system. This boundary is in the mid-cervical region for *Mo-EA* and in the hindbrain region for *Mo-10*. It should be remembered that transcription of these two genes was examined at different stages in the development of the mouse, but the apparent distinction in the sites of transcription between the two genes is reminiscent of the localized expression of *Drosophila* homoeobox genes within the ventral nerve cord of the developing fly[5,6,20].

We cannot rule out the possibility that the minor 1.7 kb transcript detected in our Northern blots might be due to cross-hybridization of the *Mo-10* probe with a product of another homoeobox gene. But we think it is more likely that the two transcripts result from differential processing of a single gene, as suggested for other mouse homoeobox genes[9,13]. Variability in transcript size could then result from use of alternative initiation, termination, or splice sites. The transcription patterns of the *Mo-10* gene will become amenable to more detailed analysis when complementary DNA probes become available. We consider it unlikely that our *in situ* hybridization experiments could detect any transcripts not shown on the Northern blots since the conditions of hybridization used *in situ* were more stringent than those used in Northern blotting[21].

The potential of the *Mo-10* gene for a role in pattern formation is clear. For example, gene expression at an abrupt boundary within the hindbrain might serve as a cue, instructing cells immediately posterior to this point to develop differently from those cells anterior to the boundary. Such a mechanism would be similar to that proposed for homoeobox genes in the bithorax complex of *Drosophila*[3,22]. From our findings, it is apparent that *Mo-10* gene expression could serve as a positional cue in this way in both ectoderm and mesoderm-derived structures.

We thank Paul Sharpe for the gift of embryo RNA. D.D. was supported by an EMBO fellowship.

The homoeobox is a 183 base-pair (bp) DNA sequence[1] conserved in several *Drosophila* genes controlling segmentation and segment identity[2–4]. Homoeobox sequences have been detected in the genome of species ranging from insects and anellids to vertebrates[5,6] and homoeobox containing genes have been cloned from *Xenopus*[7–9], mouse[10–22] and man[23]. We recently isolated human homoeobox containing complementary DNA clones, that represent transcripts from four different human genes[24]. One clone (HHO.c10) is selectively expressed in a 2.1 kilobase (kb) polyadenylated transcript in the spinal cord of human embryos and fetuses 5–10 weeks after fertilization[25]. We report the characterization of a second cDNA clone, termed HHO.c13, that represents a new homoeobox gene. This clone encodes a protein of 255 amino-acid residues, which includes a pentapeptide, upstream of the homoeo domain, conserved in other *Drosophila*, *Xenopus*, murine and human homoeobox genes. By Northern analysis HHO.c13 detects multiple embryonic transcripts, which are differentially expressed in spinal cord, brain, backbone rudiments, limb buds and heart in 5–9-week-old human embryos and fetuses, in a striking organ- and stage-specific pattern. These observations suggest that in early mammalian development homoeobox genes may exert a wide spectrum of control functions in a variety of organs and body parts, in addition to the spinal cord.

The nucleotide sequence of clone HHO.c13 is shown in Fig. 1*a*. Multiple stop codons are present in each frame up to nucleotide 230. Translation of the longest reading frame from the ATG codon at base 250 would produce a peptide sequence of 255 amino-acid residues, containing a homoeo domain extending up to 41 residues upstream from the carboxy terminus. The putative 285-bp 3′-untranslated (3′-UT) region includes a polyadenylation signal (AUUAAA) 18 nucleotides upstream from the poly(A) tail. As shown in Table 1, the sequence of HHO.c13 homoeobox is very similar (~60–75% nucleotide homology) to that of other homoeoboxes. At the level of protein sequence, the HHO.c13 homoeo domain shows particularly good homology with murine *Hox1-3* (98.3%), *Xenopus Xhox-1A* (93.4%), human HHO.c10 (90.1%) and *Drosophila Deformed* (*Dfd*) (90.2%) domain. Interestingly, the pentapeptide Leu-Pro-Asn-Thr-Lys immediately downstream from the HHO.c13 homoeo domain (Fig. 1*a*) is conserved in the *Dfd*[26,27], *Xhox-1A*[9] and *Hox1-3*[20–22] genes.

The putative protein encoded by HHO.c13 contains the pentapeptide Val-Tyr-Pro-Trp-Met, starting at amino-acid position 133 (−21 from the homoeo domain). As shown in Fig. 1*b*, this sequence is very similar to the Ile-Tyr-Pro-Trp-Met peptide in two other human unrelated cDNA clones containing homoeobox sequences, termed HHO.c1 and c8 (ref. 24). Its presence in HHO.c10 (ref. 25) cannot be assessed, because this clone is truncated within the homoeobox. The pentapeptide in HHO.c13 is conserved in *Xenopus Xhox-1A* gene[9], whereas the pentapeptide in HHO.c1 and c8 is conserved in *Drosophila Dfd*[26], and mouse m6 (P. Gruss and M. Kessel, personal communication) genes. A highly homologous Leu-Tyr-Pro-Trp-Met

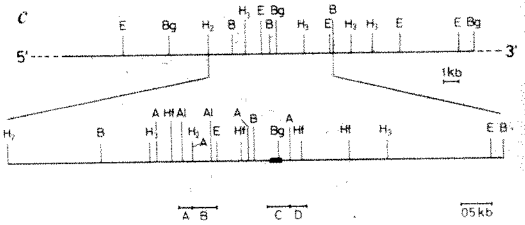

Fig. 1 *a*, Nucleotide sequence of the human cDNA clone *HHO.c13*, with the theoretical translation of its longest open reading frame. Relevant restriction endonuclease recognition sites are also shown. Arrows, three methionine codons, the putative alternative translation start sites: none of them has very good homology with the consensus sequence of initiation sites in eukaryotic genes[37]. The boxed N-terminal amino-acid sequence shows a high degree of homology with the corresponding peptide sequence of *Xenopus Xhox-1A*: Met-Arg-Met-Ser-Ser-Phe-Leu-Ile-Ser-Ser-Asn-Tyr-Val-Asp-Pro-Lys-Phe-Pro-Pro-Cys-Glu-Glu-Tyr (see ref. 9). The sequence encoding the homoeo domain is boxed. The pentapeptide Val-Tyr-Pro-Trp-Met, homologous to that found in a corresponding region of a variety of other homoeobox genes (see Fig. 1*b*) and the polyadenylation signal (ATTAAA)[38] preceding the poly(A) tail are underlined. Asterisks, the conserved pentapeptide downstream from the homoeo domain. ∇, position of the 541-bp intron. *b*, The second small homoeo domain in seven homoeobox genes from man (HHO.c13, c1 and c8), *Drosophila* (*Antp*, *Dfd* and *cad*) and *Xenopus* (*Xhox-1A*). The pentapeptide domain is boxed. Identical amino acids are in capital letters. *c*, Top: restriction endonuclease map of the *HHO.c13* transcription unit on a genomic clone (λ13G), as determined by Southern blot analysis. Bottom: A, B, C, D indicate contiguous subclones of HHO.c13 (*Pst*I/*Apa*I, *Apa*I/*Eco*RI, *Eco*RI/*Apa*I, *Apa*I/*Bam*HI), used as probes; black box, homoeobox. A, *Apa*I; Al, *Alu*I; B, *Bam*HI; Bg, *Bgl*II; E, *Eco*R1; H2, *Hin*dII; H3, *Hin*dIII; Hf, *Hin*fII; kb, kilobase pairs.

Methods. Human cDNA clones containing homoeobox sequences from simian virus 40 (SV40)-transformed human fibroblasts[24] were subcloned in the pEMBL8 plasmid[39] and sequenced as described by Maxam and Gilbert[40]. A genomic DNA clone (λ13G) was isolated from a human genomic library in λ Charon 28, digested with restriction endonucleases, electrophoresed on 0.8–1.5% agarose gels, transferred to nitrocellulose paper by Southern blotting and hybridized to nick-translated HHO.c13 clone or subclones according to standard techniques[41].

sequence is present in the *Drosophila Antp* gene[28]. The pentapeptides are located upstream from the homoeo domains starting between positions −11 and −24 (Fig. 1*b*). Similarly, a Trp-Met dipeptide is found at −18 from the unique homoeo domain of *Drosophila caudal* (*cad*) gene[29]. The pentapeptide apparently defines a second small homoeo domain, located at a short, slightly variable distance from the 5′ end of the homoeo domain itself, that is not encoded by the homoeobox containing exon[9,26,28,29].

Finally, it is noteworthy that the 23 amino-terminal residues deduced from HHO.c13 bear a striking homology to the corresponding peptide sequence encoded by *Xhox-1A*[9] (Fig. 1*a* legend).

HHO.c13 was used as hybridization probe to screen a human genomic library in λ Charon 28. A 24-kb genomic clone (λ13G) containing HHO.c13 was characterized by restriction endonuclease mapping (Fig. 1*c*) and partially sequenced (not shown). The HHO.c13 coding region is interrupted by a 541-bp intron, located upstream from the homoeobox (Fig. 1*a*, *c*).

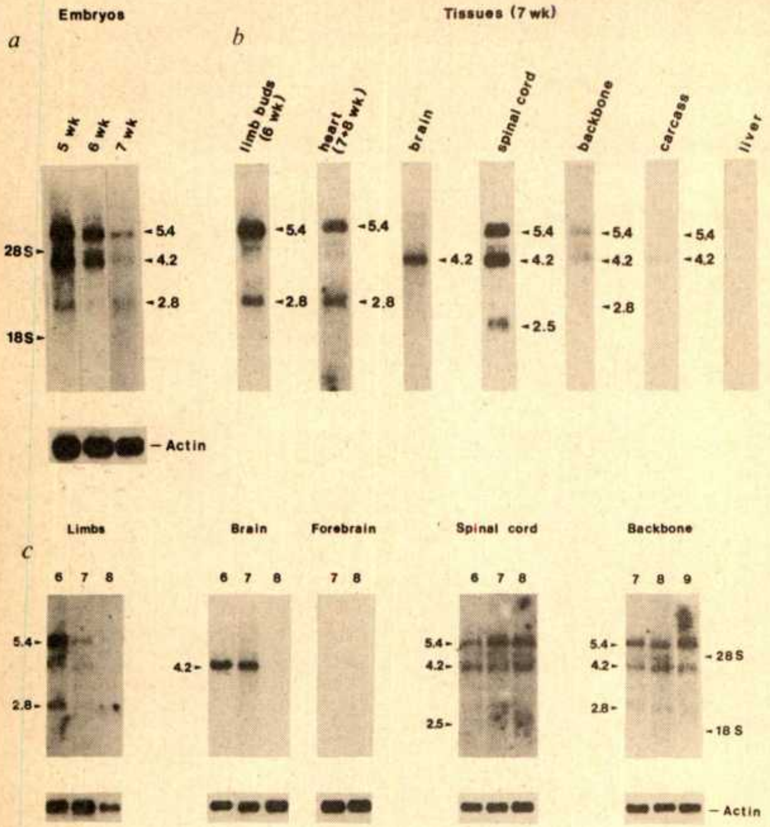

Fig. 2 *a*, Northern blot analysis of the expression of *HHO.c13* in poly(A)$^+$ RNA from whole human embryos at 5, 6 and 7 weeks after fertilization. The relative mobility of 28S and 18S rRNA is shown as size markers. Sizes are in kb. *b*, Expression of HHO.c13 in poly(A)$^+$ RNA obtained from pools of organs or body parts dissected from human embryos of 7 weeks. Limb buds were obtained at 6 weeks, hearts pooled at 7 and 8 weeks. Brain was dissected from spinal cord at the level of the pontine flexure, separating metencephalon from myelencephalon. 'Carcass' indicates poly(A)$^+$ RNA from a control embryo deprived of limbs, brain and spinal column. *c*, Expression of HHO.c13 in limb buds or limbs, brain, spinal cord and backbone from human embryos of 6, 7, 8 and 9 weeks, as analysed by Northern blot hybridization of poly(A)$^+$ RNA. Sizes are in kb. The forebrain contains the cerebral hemispheres, dissected from midbrain (mesencephalon) and hindbrain (metencephalon).

Methods. Total RNA was extracted by the guanidinium thiocyanate technique[42], poly(A)-selected by one passage on oligo (dT)-cellulose columns, run in 2-3 μg aliquots on 1.0% agarose-formaldehyde gels[41] and transferred to nitrocellulose or nylon membranes by Northern capillary blotting[43]. Filters were hybridized to 10^7 c.p.m. of HHO.c13 probe labelled by nick-translation to specific activity of $3\text{-}6\times10^8$ d.p.m. per μg, washed at high stringency (final wash 0.1 × SSC, 0.1% SDS at 60 °C) and exposed for 1-7 days to Kodak XR-5 X-ray films in X-omatic intensifying screen cassette. Filters were rehybridized to a chicken β-actin probe[44] for normalization.

Chromosome mapping by standard procedures indicates that the HHO.c13 gene is localized on the long arm of chromosome 2 (K. Hübner and C. Croce, personal communication). These data indicate that the HHO.c13 clone defines a new human homoeobox gene, unrelated to the cluster previously identified on chromosome 17[12,13].

We then used the HHO.c13 cDNA clone as a probe to analyse the expression of the gene in human embryonic and early fetal development. Embryos and fetuses were obtained virtually intact from legal curettage abortions, from 5-9 weeks after fertilization[30]. The age of embryos (5-8-week-old) was established by morphological staging according to multiple criteria[31]; the youngest were from the first part of the fifth week (total length 7-9 mm, developmental stage 13-14). Fetuses (9-week-old) were staged on the basis of standard age/crown-rump length (CRL) plots[32]. The dating error was about ±2 days (see also refs 25, 30, 31).

Northern blot analysis of poly(A)$^+$ RNA obtained from whole embryos at 5, 6 and 7 weeks (Fig. 2*a*) indicates that the HHO.c13 gene is expressed in at least three transcripts of 5.4, 4.2 and 2.8 kb: their abundance, however, sharply declines between the fifth and seventh weeks. No signal was detected in Northern blots of corresponding poly(A)$^-$ RNA (not shown). Poly(A)$^+$ RNA was probed with cDNA subclones with or without the homoeobox (probes C or B and D respectively, see Fig. 1*c*): in all cases the pattern was virtually identical (not shown), thus excluding cross-hybridization with transcripts from other homoeobox containing genes. Note that the noncoding strand of the central 170-bp *Eco*RI-*Bgl*II fragment of HHO.c13 (see Fig. 1*a*) detects all three major transcripts, whereas the coding strand does not show any major hybridization band (data not shown).

We then analysed the expression of HHO.c13 in different organs or body parts, dissected by microsurgery from 7-week-old embryos (CRL 16-20 mm, stage 18-19); samples from different specimens were pooled when necessary. Limb buds were obtained at 6 weeks (CRL 10-15 mm, stage 16-17), hearts pooled at 7-8 weeks (CRL 20-20 mm, stage 20-23). Brain and spinal cord, dissected free of contaminating tissues, were separated at the level of the pontine flexure, which delimits metencephalon from myelencephalon (*medulla oblongata*). As shown in Fig. 2*a*, *b*, human embryos show a differential, tissue-specific pattern of expression of the HHO.c13 gene, both quantitatively and qualitatively. In particular, (1) 5.4- and 2.8-kb transcripts are predominantly expressed in limb buds and heart; (2) only the 4.2-kb band is observed in brain, but (3) 5.4-, 4.2- and 2.5-kb transcripts are detectable in spinal cord, the last showing the characteristic broad appearance of other cord-specific homoeobox-containing transcripts (ref. 25 and our unpublished results); (4) 5.4-, 4.2- and a faint 2.8-kb bands are observed in the backbone rudiment; (5) 4.2- and to a lesser extent 5.4-kb transcripts are detectable in RNA from control embryos ('carcass'), deprived of limbs, brain and spinal column; (6) no signal is observed in liver.

To define whether the expression of HHO.c13 transcripts is stage-specific, we have analysed poly(A)$^+$ RNA from limb buds or limbs, brain, spinal cord and backbone at 6, 7 and 8 weeks (Fig. 2*c*).

Expression of the 5.4- and 2.8-kb transcripts in limbs declines dramatically between the sixth and the seventh weeks, and almost disappears by eight weeks. This correlates with the morphogenetic progression of limb development, which starts late in the fifth week and is almost complete at the end of the eight week[31]. Significant expression of HHO.c13 transcripts is thus confined to the limb bud development stage.

The 4.2-kb transcript observed in the brain is expressed at constant or possibly slightly declining level between six and seven weeks, but almost disappears by eight weeks. Dissection of forebrain (developing cerebral hemispheres) from midbrain (mesencephalon) and hindbrain (methencephalon) indicates that at seven weeks expression of this transcript is confined to the two latter structures. We could not discover whether this spatial restriction also occurs at 6 weeks; if so, it might be related to development of well-defined structures in the 6-7 week period (for example, the cerebellum).

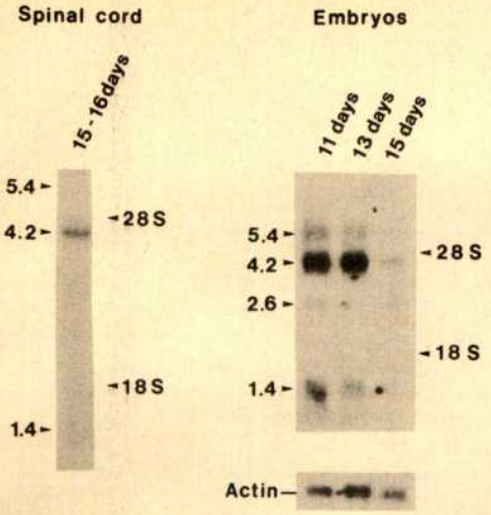

Fig. 3 Northern blot analysis of the expression of a HHO.c13 rat homologue. Poly(A)$^+$ RNA was obtained from both spinal cord at 15–16 days from fertilization (5 μg per lane, left panel) and embryos *in toto* at 11, 13 and 15 days (3 μg, right panel). Relevant transcripts are indicated. Sizes are in kb.

Table 1 Homologies between the HHO.c13 homoeobox and the corresponding region of other genes or clones, at nucleotide and amino-acid level

Expression of 5.4-, 4.2- and 2.5-kb transcripts in the spinal cord, and 5.4-, 4.2- and 2.8-kb transcripts in the developing backbone, appear constant throughout the 6–8 and 7–9 week period respectively. It is worth noting that expression of at least one other homoeobox gene (HHO.c10 or *Hu-1*) is apparently constant in the spinal cord in the same period of human embryogenesis[25].

Earlier stages of development were explored in the rat. We first analysed poly(A)$^+$ RNA from spinal cord of rat embryos at 15–16 days from fertilization, corresponding to ∼7 weeks in human development. As shown in Fig. 3, HHO.c13 hybridizes to at least three transcripts of 5.4-, 4.2- and 1.4-kb, presumably from a rat gene homologous to HHO.c13. We then extended the analysis to poly(A)$^+$ RNA from whole rat embryos at developmental stages from day 11 (total length 1.5–2.0 mm, 13 somites) to 15 (CRL 9 mm, >40 somites)[33], (approximately the beginning of the fourth and the end of the sixth week of human embryogenesis)[31]. Transcripts of 5.4-, 4.2-, 2.6- and 1.4-kb were observed (Fig. 3), with constant expression from day 11–13 decreasing by 50% at day 15. Thus the HHO.c13 gene is already active in rat (and possibly human) embryos at a stage of development immediately after the complete fusion of the neural tube.

The transcripts from human embryos are significantly longer than the cDNA clone (isolated from a simian virus 40 (SV40)-transformed adult fibroblast cDNA library[34]). Preliminary mapping data on embryonic RNAs (not shown) indicate that the major 5.4- and 4.2-kb transcripts terminate ∼2 kb downstream from the HHO.c13 polyadenylation site, whereas 2.8-kb transcripts do not extend further downstream. If our cDNA clone is the 3′ portion of the 2.8 kb transcript, it may be suggested that this transcript has an unusually long 5′-UT sequence.

In *Drosophila* the homoeobox genes, mainly organized in multigene clusters, are involved in the control of crucial developmental processes, as the determination of the number and fate of individual body segments[1]. In amphibians and mammals homoeobox genes, often organized in multigene clusters[15,18,21,23], might act similarly. Studies on early mammalian development show that a variety of homoeobox genes are expressed in murine[14–18,21,22] and human[25] embryos, often with a time-related pattern[14–18,21,22]. Analysis of single organs from mammalian embryos or newborns reveals selective expression of homoeobox genes in the spinal cord[14,19,25], which typically constitutes a metameric structure: in particular, *Hox-3* is expressed in a spatially restricted pattern[19], reminiscent of that observed for other homoeobox genes in *Drosophila*[35,36].

Our observations suggest that homoeobox genes may exert a wide spectrum of control functions in the embryonic and early fetal development of mammals, not only in the spinal cord, but also in a variety of other organs and body parts that follow basically different patterns of morphogenesis.

We thank Drs G. Cossu and G. Macino for helpful discussion, Dr V. Fidanza for cooperation in computer analysis and Mrs V. Autuori for expert assistance in rat embryo dissection. This work was supported by grants from Consiglio Nazionale delle Ricerche, Progetti Finalizzati 'Ingegneria Genetica e Basi Molecolari delle Malattie Ereditarie' to E.B. and C.P. (grant no. 85.01425.51), 'Oncologia' to E.B., F.M. (85.02244.44) and C.P. (85.02560.44), 'Medicina Preventiva' to C.P. (85.00707.56).

Cross-regulatory interactions among the gap genes of *Drosophila*

Herbert Jäckle, Diethard Tautz, Reinhard Schuh, Eveline Seifert & Ruth Lehmann*

Spemannstr. 35/III, D-7400 Tübingen, FRG

Segmentation of the *Drosophila* embryo involves expression of several classes of zygotic genes in response to positional information of maternal origin[1]. Zygotic expression of the gap genes is thought to be required for the subdivision of the embryo into several units of adjacent segments; pair-rule genes establish a repeat unit length of two segments and segment polarity genes specify parts of the single segment[2–5]. The positional information provided by the three classes of segmentation genes is interpreted for the establishment of segment identity using the homoeotic genes[6–10]. Molecular probes for several segmentation and homoeotic genes reveal a temporal and spatial pattern of gene expression in the young embryo[11–18]. Changes in the pattern of expression of these genes in mutant embryos provide evidence for a network of interactions among homoeotic and pair-rule genes[19–23] that itself depends on the activity of gap genes[24–27]. We show here that the spatial limit of gap gene expression depends on bilateral interactions among gap genes.

Gap mutant embryos lack a number of adjacent segments which define the domains of the wild-type gene requirement. Based on the deletion pattern (Fig. 1), zygotic *hunchback* (*hb*) activity is required for normal establishment of gnathal and thoracic segments (up to T3), *Krüppel* (*Kr*) for thoracic and anterior abdominal segments (T1–A5), and *knirps* (*kni*) for the abdominal segments A1 to A7 (ref. 2). In a first and naive view, one might expect expression of gap genes in overlapping domains which themselves correspond to the deleted regions in the mutant phenotypes, as shown before for members of the pair-rule class of segmentation genes[13,14,18]. According to a theoretical model by Meinhardt[28], however, the expression of gap genes in response to positional information of maternal origin occurs in adjacent, non-overlapping domains. Each domain should be smaller than the deleted region in the mutant embryo. The limits of the regions where gap genes are expressed (at blastoderm stage) would then provide additional positional cues for the expression of other segmentation genes in a hierarchical order. The model predicts further that these borders

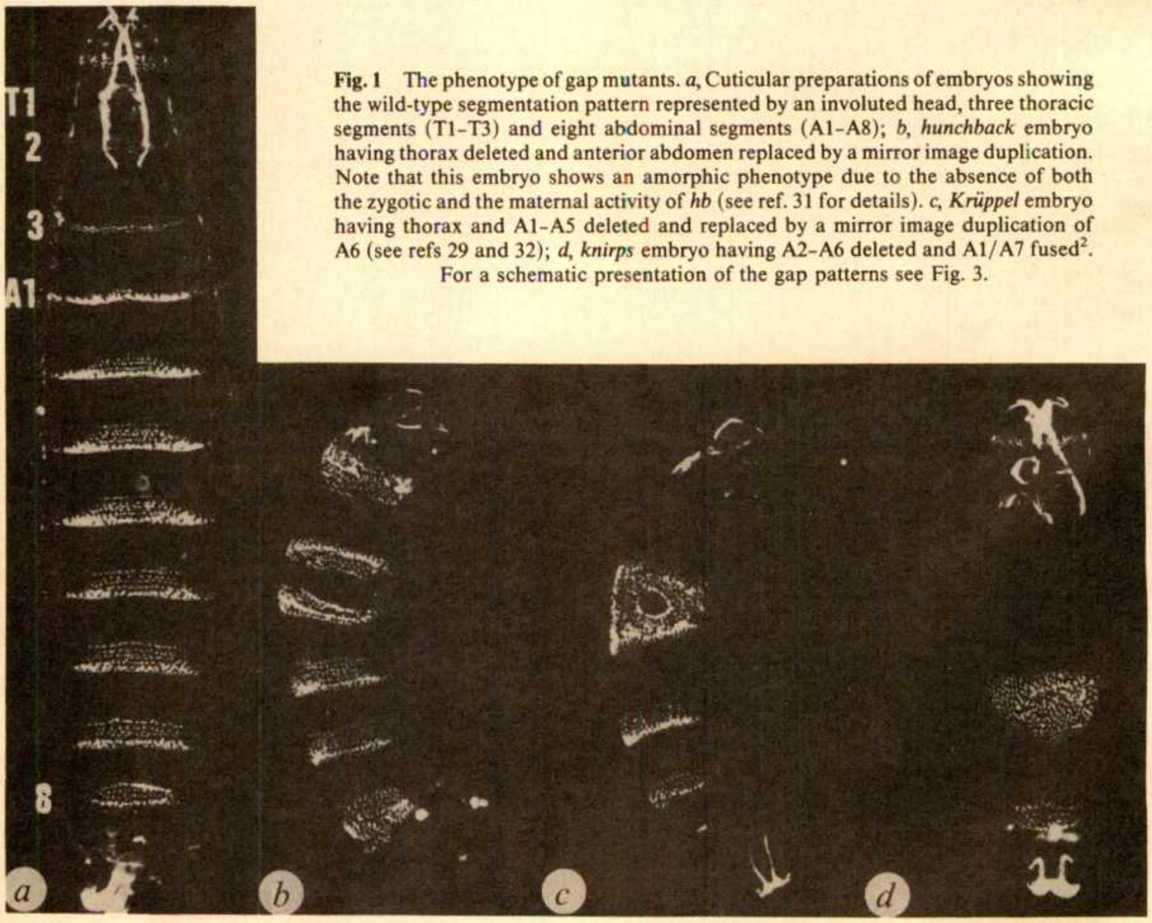

Fig. 1 The phenotype of gap mutants. *a*, Cuticular preparations of embryos showing the wild-type segmentation pattern represented by an involuted head, three thoracic segments (T1–T3) and eight abdominal segments (A1–A8); *b*, *hunchback* embryo having thorax deleted and anterior abdomen replaced by a mirror image duplication. Note that this embryo shows an amorphic phenotype due to the absence of both the zygotic and the maternal activity of *hb* (see ref. 31 for details). *c*, *Krüppel* embryo having thorax and A1–A5 deleted and replaced by a mirror image duplication of A6 (see refs 29 and 32); *d*, *knirps* embryo having A2–A6 deleted and A1/A7 fused[2]. For a schematic presentation of the gap patterns see Fig. 3.

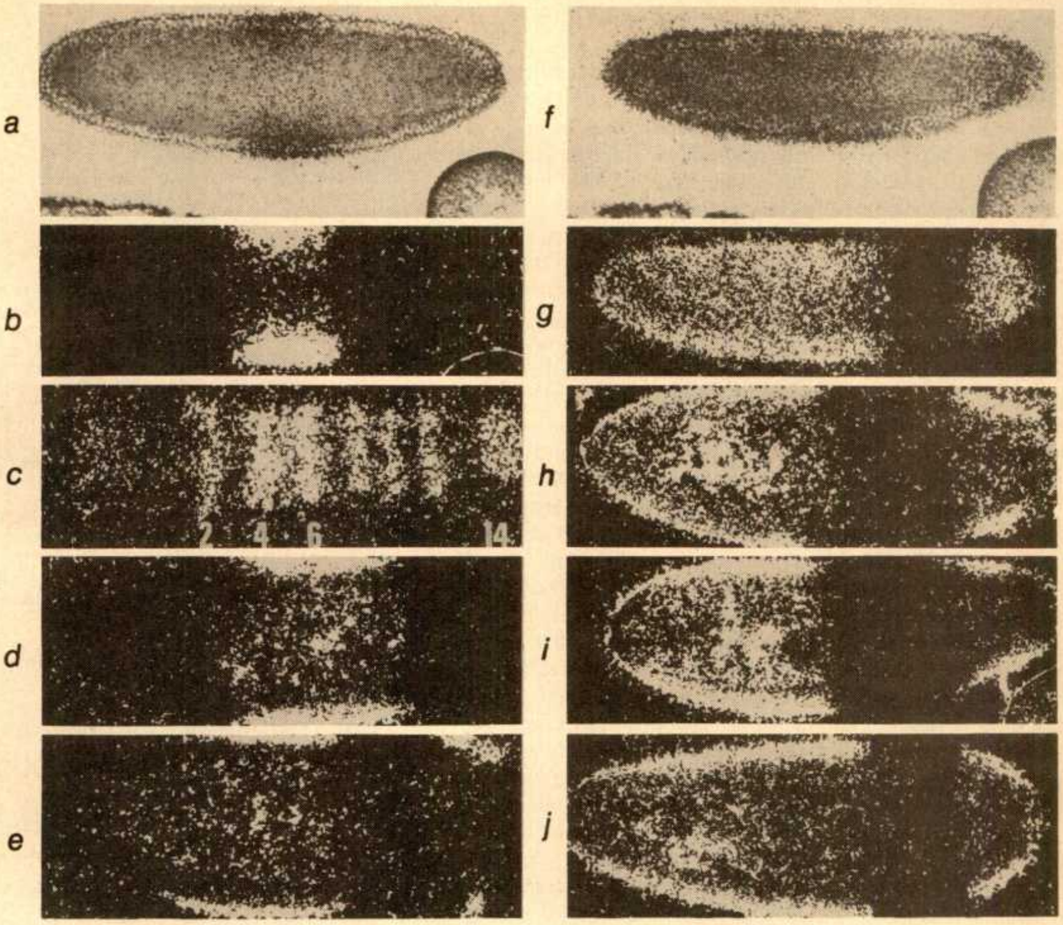

Fig. 2 *In situ* localization of Kr^+ and hb^+ transcripts in gap mutant embryos after the thirteenth nuclear division. *a*, *b*, Kr^+ expression in blastoderm stage wild-type embryos; *a*, bright field photograph of a parasagittal section and *b*, corresponding dark-field photograph to visualize the *in situ* hybridization pattern of the *Kr* probe. Note that even after overexposure, the Kr^+ anterior domain remains within the borders of 12–14 cells[17]. *c*, *In situ* pattern of a mixed *fushi tarazu* (*ftz*) and Kr^+ probe hybridized to the tangential section of the embryo shown in *a*. Note that the Kr^+ domain (low specific activity) overlaps *ftz*-stripes 2 and 4 and thus corresponds to the approximate limits of parasegments 4–6 (indicated by numbers, ref. 14). Kr^+ expression in *d*, kni^- and *e*, hb^- embryos. Note the broadening of Kr^+ expression into the adjacent gap gene domain if the corresponding gene activity is absent. *f*, Bright field and *g*, corresponding dark field photograph of wild type section between *a* and *c* which was hybridized with a mixed hb^+/Kr^+ probe. *h*, parasagittal section (dark field) of the same embryo hybridized with the hb^+ probe. Expression of hb^+ in: *i*, kni^- and *j*, Kr^- embryos. Note a broadening of the hb^+ domain in Kr^- but not in kni^- embryos. Orientation of embryos is anterior left and ventral bottom. Note that yolk cells express both Kr^+ and hb^+ (ref. 17, and D.T., unpublished).

Methods. Embryos from wild-type, *Kr* AP1/SM1 (ref. 29), *kni* FC13/TM3 or *hb* Df(3R)p13/TM3 (ref. 33) parents were collected within 2 h after deposition and kept for 1 h at 26 °C. Serial sections were prepared and subsequently handled as described[17], except that they were hybridized *in situ* using nick-translated ^{35}S-labelled hb^+ and/or Kr^+ probes ($2\text{–}5\times10^7$ c.p.m. per μg DNA). Exposure was 10–20 days in the cold. For positional reference in the embryo, the mixed ftz/Kr^+ probe was hybridized to wild-type and gap mutant sections alternating with Kr^+ and/or hb^+ hybridized sections (see Fig. 3 legend). This allowed, in addition to statistics, hb^- embryos to be recognized by the lack of hb^+ transcripts and a changed ftz^+ pattern[26]; Kr^- by the lack of Kr^+ transcripts and a changed ftz^+ pattern[26]. Embryos which were kni^- were identified by the broadened Kr^+ domain in about a quarter of embryos which have the changed ftz^+ pattern[26]. The limit of resolution of Kr^+ and hb^+ expression on our sections is about two cells.

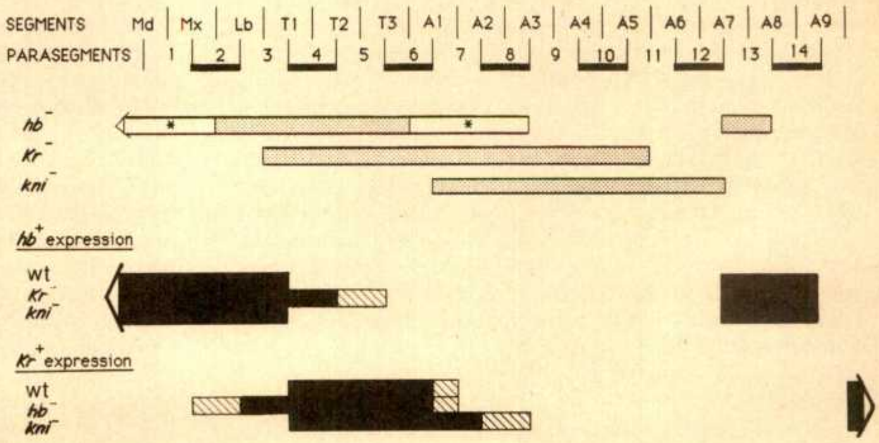

Fig. 3 Summary of the spatial distribution of hb^+ and Kr^+ expression in gap mutant embryos. Schematic diagram of the patterns of hb^+ transcripts in wild type (wt), Kr^- and kni^- embryos, and Kr^+ transcripts in wild type (wt), hb^- and kni^- embryos, respectively. Black bars, areas of expression, dashed areas, subjective limits of resolution. Above, the deletion of adjacent segments in the different gap mutant embryos is indicated by dotted bars. Asterisks, gap extension in *hb* embryos in the absence of the maternal hb^+ complement[31]. For a positional reference of Kr^+ and hb^+ domains in wild-type embryos, segments and parasegments 1–14 were determined by use of the *fushi tarazu* probe, which is localized in parasegments 2, 4, etc. (thin black bars, see Fig. 2*c*) as described[14]. The analysis is within the limits of two cells and it is based on a minimum of 16 embryos with the respective genotype. Md, mandibular segment; Mx, maxillary segment; Lb, labial segment; T1–T3, thoracic segments; A1–A8, abdominal segments.

are established by interaction between pairs of gap genes, the activities of which are maintained in their domains by autocatalytic and competitive processes[28].

Recent cloning of Kr^{29} and *hb* (D.T., unpublished) provides molecular probes to analyse the spatial pattern of Kr^+ and hb^+ expression by *in situ* hybridization to gap mutant embryos (Fig. 2). Adjacent sections of early blastoderm stage embryos were probed with a mixed Kr^+/hb^+ (Fig. 2*f,g*) or Kr^+/*fushi tarazu* probe to provide positional reference points. This allowed us to map the 12-14 cell wide domain of Kr^+ expression in parasegments 4-6 and the anterior domain of hb^+ expression (Fig. 2*j*) anterior to *Kr* (Fig. 2*a–c*; *f-h.*) The size and the borders of the *Kr* and the *hb* domains were changed in gap mutant embryos, but only if the activity of the gap gene in the adjacent domain was missing. In amorphic kni^- embryos, Kr^+ expression extends 6-8 cells posterior to its normal boundary (Fig. 2*d*), into the region corresponding to parasegment 8 or segment A3 in the wild type embryo (Fig. 3). Expression of hb^+, in contrast to *Kr*, appears unchanged in kni^- embryos (Fig. 2*i*). But the hb^+ domain broadens 6-8 cells posteriorly if Kr^+ activity is absent (Fig. 2*j*). It forms a new posterior boundary in a region which is normally parasegment 5 or segment T3 (Fig. 3). Kr^+ expression in hb^- embryos has a complementary effect; the Kr^+ expression extends 6-8 cells anteriorly, if hb^+ activity is missing in the embryo (Fig. 2*e*). The new anterior boundary of Kr^+ appears in a region which corresponds to parasegment 2 or maxilla in normal embryos (Fig. 3). These results indicate that the normal domain of gap gene expression is dependent on gap gene activity in the adjacent domains. This suggests cross-regulation of gap gene activity at the same hierarchical level as has been proposed as a key prediction in Meinhardt's model[28].

There is a second, posterior domain of Kr^+ (at late blastoderm; see details in ref. 17) and hb^+ expression (Fig. 2; and D.T., unpublished) that relates to the fusion of abdominal segments A7 and A8 in late hb^- embryos, and to the lack of malphighian tubules in late Kr^- embryos. The spatial characteristics of these posterior domains remain unaffected in each of the gap mutant embryos analysed (Fig. 2 and data not shown). This suggests that the control of expression in the posterior domain is different from anterior, possibly depending on different maternal cues, other gap genes which may act in that region and/or a feedback control by the activities of other segmentation genes. Such activities may also be required to establish the new anterior and posterior limits of Kr^+ activity in hb^- and kni^- embryos, respectively. Neither of these boundaries have any obvious morphological correspondence in the phenotype of any known gap mutant embryo. Thus the *hb* posterior border in Kr^- embryos may relate to the complementary extension of the kni^+ domain and hence an interaction of *hb* and *kni* in the absence of the Kr^+ gene product, as predicted by Meinhardt[28].

We do not understand the molecular basis of these interactions between gap genes. Because the *Kr* gene product shares homology with the DNA-binding domain of transcription factor[30], it is tempting to speculate that gap gene products may regulate each other's activity through mutual or competitive DNA-binding interactions as has been suggested for cross-regulation of the expression of homoeobox containing genes[21,22].

The combination of complementary DNA expression and single-channel current analysis provides a powerful tool for studying the structure–function relationship of the nicotinic acetylcholine receptor (AChR) (refs 1–5). We have previously shown that AChR channels consisting of subunits from different species, expressed in the surface membrane of *Xenopus* oocytes, can be used to relate functional properties to individual subunits[4]. Here we report that, in extracellular solution of low divalent cation concentration, the bovine AChR channel has a smaller conductance than the *Torpedo* AChR channel. Replacement of the δ-subunit of the *Torpedo* AChR by the bovine δ-subunit makes the channel conductance similar to that of the bovine AChR channel. To locate the region in the δ-subunit responsible for this difference, we have constructed chimaeric δ-subunit cDNAs with different combinations of the *Torpedo* and bovine counterparts. The conductances of AChR channels containing chimaeric δ-subunits suggest that a region comprising the putative transmembrane segment M2 and the adjacent bend portion between segments M2 and M3 is involved in determining the rate of ion transport through the open channel.

The *Torpedo* and bovine AChRs were expressed in *Xenopus laevis* oocytes by microinjection of the respective α-, β-, γ- and δ-subunit-specific messenger RNAs synthesized by transcription *in vitro* of the cloned cDNAs (refs 2, 4, 6). Figure 1*a* compares the sizes of acetylcholine(ACh)-activated elementary inward currents mediated by the *Torpedo* (round symbols) and bovine

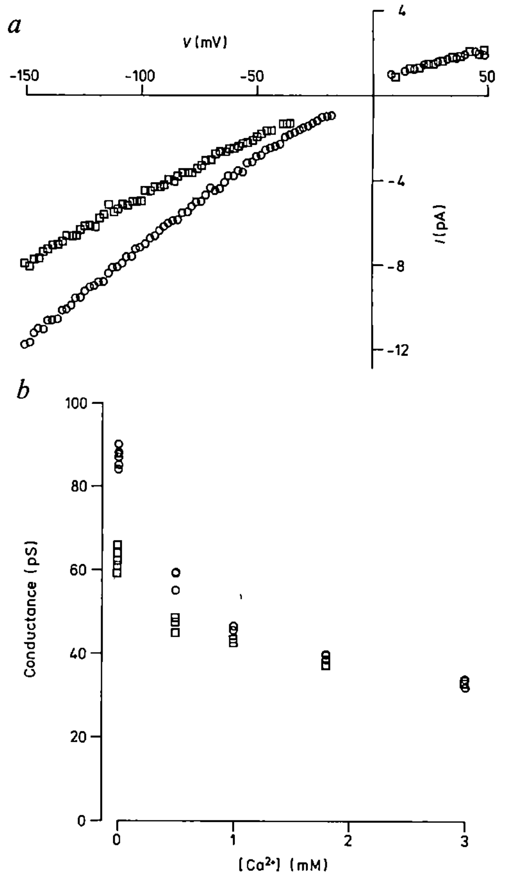

Fig. 1 Conductance properties of the *Torpedo* and bovine AChR channels produced in *Xenopus* oocytes *a*, Single-channel *I*-*V* relations of (○) *Torpedo* and (□) bovine AChR channels produced in *Xenopus* oocytes injected with the respective α-, β-, γ- and δ-subunit-specific mRNAs All single-channel *I*-*V* relations were measured at 12 ± 1 °C in cell-attached patches The pipette was filled with 30 mM KCl, 70 mM KF, 1 mM $MgCl_2$, 10 mM EGTA and 10 mM HEPES (*p*H 7.2), the concentration of free Mg^{2+} is calculated to be less than 1 μM, using a stability constant for MgEGTA of 1.6×10^5 M^{-1} This solution is referred to as low divalent cation extracellular solution (LDCS) Each point represents the mean amplitude of at least four elementary currents measured during either rampwise or stepwise changes of the voltage applied to the patch pipette In experiments with LDCS in the pipette, *I*-*V* relations were sometimes slightly bent in the inward direction at potentials more negative than −150 mV Conductances were measured as slope conductances between −40 mV and −150 mV membrane potential by linear regression The conductances of the *Torpedo* and bovine AChR channels illustrated are 88 pS ($r^2 = 0.997$) and 61 pS ($r^2 = 0.995$), respectively In experiments with low K^+ pipette solution (10 mM KCl, 5 mM EGTA and 10 mM HEPES (*p*H 7.2)), the slope conductances were measured at membrane potentials between −90 mV and −200 mV *b*, Ca^{2+} concentration dependence of single-channel K^+ conductances Slope conductances measured between −40 mV and −150 mV membrane potential are shown as a function of Ca^{2+} concentration in the pipette LDCS as in *a* In experiments with different Ca^{2+} concentrations, $CaCl_2$ was added to 100 mM KCl and 10 mM HEPES (*p*H 7.2) to give the desired Ca^{2+} concentration Each point represents measurement of the slope conductance in one patch ○, *Torpedo* AChR channels, □, bovine AChR channels

Methods The *Torpedo* and bovine AChR subunit-specific mRNAs were synthesized *in vitro* as described previously[2,4,6], except that the transcription was primed[19] with the cap dinucleotide G(5′)ppp(5′)G (0.5 mM) and that the bovine δ-subunit-specific mRNA was synthesized using *Eco*RI-cleaved pSPcδ2 as template (for construction, see Fig 3 legend) *Xenopus laevis* oocytes were injected with specified combinations of the *Torpedo* and bovine AChR subunit-specific mRNAs and incubated for 3-5 days[4] Single-channel current measurements were made from cell-attached membrane patches as described[20] The oocyte membrane potential was measured by an intracellular microelectrode and added to the pipette potential to give the patch transmembrane potential The potential across the patch was voltage clamped via the patch pipette to the desired command potential In each experiment, the current step sizes were measured during rampwise or stepwise changes of the patch membrane potential between −175 mV and 75 mV Each *I*-*V* relation is based on 300-1,400 amplitude determinations in the voltage range between −150 mV and 50 mV Current records were sampled at 20 kHz after low-pass filtering at 2 or 3 kHz (−3 dB) and analysed by a semiautomatic procedure The patch membrane potential was sampled at 0.6 kHz Single-channel current amplitudes within 2 mV intervals were pooled

(square symbols) AChR channels as measured in cell-attached patches with a potassium-rich pipette solution at low (<1 μM) divalent cation concentration The single-channel current-voltage (*I*-*V*) relations show that the K^+ conductance of the *Torpedo* AChR channel (87 ± 2 pS, mean ± s.d.), measured as slope conductance between −40 mV and −150 mV membrane potential, is larger than that of the bovine AChR channel (62 ± 2 pS) (Fig 3*b*) When the Ca^{2+} concentration in the pipette is increased, the conductances of both the *Torpedo* and bovine AChR channels decrease and the two tend to equalize (Fig 1*b*) At Ca^{2+} concentrations ≥ 1.8 mM, both channels are equally conductive A decrease in the conductances of the *Torpedo* and bovine AChR channels was observed in the presence of added extracellular Ca^{2+} with Na^+, Cs^+ or Li^+ as the permeant cation The reduction in single-channel conductance was also observed when the extracellular divalent cation was Mg^{2+}, Sr^{2+} or Ba^{2+} For both channels the effect of Mg^{2+} was more pronounced than that of the other divalent cations The K^+ conductances at low extracellular divalent cation concentration represent high concentration limits of these conductances since varying the K^+ concentration in the pipette between 10 mM and 100 mM altered the channel conductance of both the *Torpedo* and the bovine AChR by <10%

One explanation for the dependence of the AChR channel conductance on extracellular divalent cations is that it reflects changes in the effective negative surface charges on the receptor[7,8] At low divalent cation concentration, permeant cations would be concentrated at the mouth of the channel as compared with the bulk solution This concentration effect could cause ion saturation of the channel even when the cation concentration in the bulk solution is low (10 mM) Other mechanisms, such as blocking of monovalent cation flow by divalent cations, probably play a role at higher divalent cation concentrations[9] We have used the difference in conductance observed at low divalent cation concentration in an attempt to identify those parts of the AChR molecule important for forming the channel

To determine whether a particular subunit is responsible for this difference in conductance between the *Torpedo* and bovine AChR channels, we constructed hybrid AChRs by injecting *Xenopus* oocytes with the bovine α-subunit-specific mRNA and

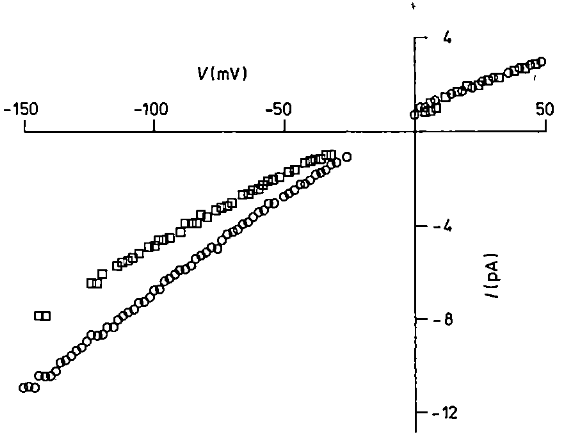

Fig 2 Single-channel *I*-*V* relations of α-hybrid (○) and δ-hybrid (□) AChR channels The hybrid AChR channels were produced in *Xenopus* oocytes by injection of the specified combinations of the *Torpedo* and bovine subunit-specific mRNAs Experimental details as in Fig 1*a*, pipettes filled with LDCS The slope conductances of the α-hybrid and δ-hybrid AChR channels shown are 84 pS ($r^2 = 0.998$) and 64 pS ($r^2 = 0.996$), respectively

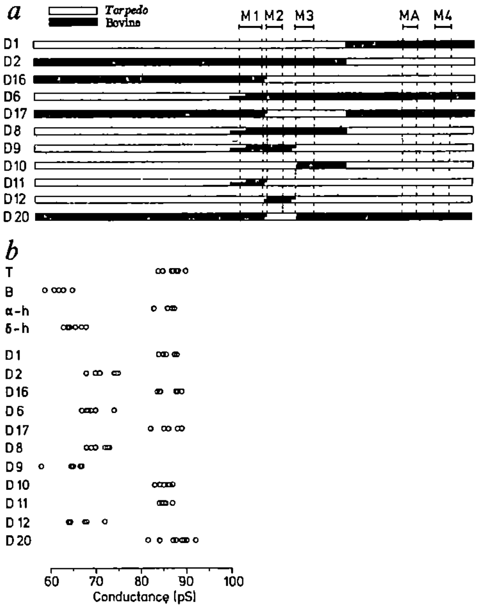

Fig 3 Location of a δ-subunit region determining the rate of ion transport through the AChR channel *a*, Structures of chimaeric δ-subunits composed of *Torpedo*[21] and bovine[15] sequences The structures of chimaeric δ-subunits, including the amino-terminal signal sequence, are diagrammatically shown such that the hydrophobic segments M1–M4 and the amphipathic segment MA (refs 2, 10–14) are aligned[15], the fact that the bovine δ-subunit is smaller by six amino acids than the *Torpedo* δ-subunit is ignored Open boxes, amino-acid sequences derived from the *Torpedo* δ-subunit, filled boxes, those from the bovine δ-subunit Junctional sequences common to the two δ-subunits are indicated by both boxes The compositions of the individual chimaeric δ-subunits are as follows (T and B denote the *Torpedo* and the bovine δ-subunit, respectively and the numbers in parentheses indicate amino-acid numbers[15,21], the junctional sequences common to the two δ-subunits are represented by amino acid numbers of the *Torpedo* δ-subunit) D1, T(−21–350) and B(350–495), D2, B(−21–350) and T(352–501), D16, B(−21–252) and T(254–501), D6, T(−21–231) and B(231–495), D17, B(−21–252), T(254–350) and B(350–495), D8, T(−21–231), B(231–350) and T(352–501), D9, T(−21–231), B(231–284) and T(286–501), D10, T(−21–292), B(292–350) and T(352–501), D11, T(−21–231), B(231–252) and T(254–501), D12, T(−21–256), B(256–284) and T(286–501), D20, B(−21–252), T(254–292) and B(292–495) *b*, Single-channel conductances of the *Torpedo* AChR (T), bovine AChR (B), α-hybrid AChR (α-h), δ-hybrid AChR (δ-h) and AChRs with chimaeric δ-subunits The AChRs with chimaeric δ-subunits were produced in *Xenopus* oocytes by injection of the respective chimaeric δ-subunit-specific mRNAs together with the *Torpedo* α-, β- and γ-subunit-specific mRNAs Each point represents measurement of slope conductance in one patch Experimental details as in Fig 1*a*, pipettes filled with LDCS The mean conductances of the individual AChR channels are as follows *Torpedo* AChR, 87±2 pS (mean±s d , $n=7$), bovine AChR, 62±2 pS ($n=5$), α-hybrid AChR, 86±2 pS ($n=4$), δ-hybrid AChR, 65±2 pS ($n=6$), AChR-D1, 86±2 pS ($n=5$), AChR-D2, 72±3 pS ($n=6$), AChR-D16, 86±2 pS ($n=6$), AChR-D6, 69±3 pS ($n=6$), AChR-D17, 86±3 pS ($n=5$), AChR-D8, 71±2 pS ($n=6$), AChR-D9, 64±4 pS ($n=5$), AChR-D10, 85±1 pS ($n=6$), AChR-D11, 85±1 pS ($n=5$), AChR-D12, 67±3 pS ($n=5$), AChR-D20, 88±3 pS ($n=8$)

Methods The 1 113-base-pair (bp) *Sma*I fragment from pSPcδ (ref 4) was ligated with the synthetic *Hin*dIII linker 5′-ACAAGCTTGT-3′, cleaved with *Hin*dIII and *Acc*I, and the resulting 423-bp fragment was isolated The 5 0-kilobase (kb) *Hin*dIII fragment from pSPcδ was treated with T4 DNA polymerase in the presence of the four deoxyribonucleoside triphosphates, ligated with the synthetic *Eco*RI linker 5′-GGAATTCC-3′ and cleaved with *Eco*RI and *Acc*I The resulting 1 5-kb fragment was ligated with the 423-bp fragment described above and the 3 0-kb *Hin*dIII–*Eco*RI fragment from pSP64 (ref 22) to yield pSPcδ2 The ~830-bp *Sma*I–*Eco*RI fragment from pSPcδ2, the 4 2-kb *Bam*HI–*Eco*RI fragment from pSPδ (ref 2) and the synthetic oligodeoxyribonucleotide

were ligated to yield pSPD12 The 326-bp *Acc*I–*Fok*I fragment from pSPD5 and the 328-bp *Fok*I–*Bam*HI fragment from pSPD11 were ligated and cleaved with *Acc*I and *Bam*HI The resulting 654-bp fragment was ligated with the 4 0-kb *Bam*HI–*Pst*I and 150-bp *Pst*I–*Acc*I fragments from pSPD5 to yield pSPD16 The 326-bp *Acc*I–*Fok*I fragment from pSPD5 and the 328-bp *Fok*I–*Bam*HI fragment from pSPD11 were ligated and cleaved with *Acc*I and *Bam*HI The resulting 654-bp *Acc*I–*Bam*HI fragment was ligated with the 3 9-kb *Bam*HI–*Hin*dIII and 423-bp *Hin*dIII–*Acc*I fragments from pSPD7 to yield pSPD17 The 4 7-kb *Nco*I–*Aat*II fragment from pSPcδ2, the 153-bp *Aat*II–*Dde*I fragment isolated from the 363-bp *Aat*II–*Bam*HI fragment from pSPD11 and the 102-bp *Dde*I–*Nco*I fragment isolated from the 146-bp *Pst*I–*Nco*I fragment from pSPD4 were ligated to yield pSPD20 Those regions of the constructed plasmids derived from the synthetic oligodeoxyribonucleotides were sequenced[23] to ensure the constructions The chimaeric δ-subunit-specific mRNAs were synthesized as described in the legend to Fig 1, using *Eco*RI-cleaved plasmids carrying the respective cDNAs as templates

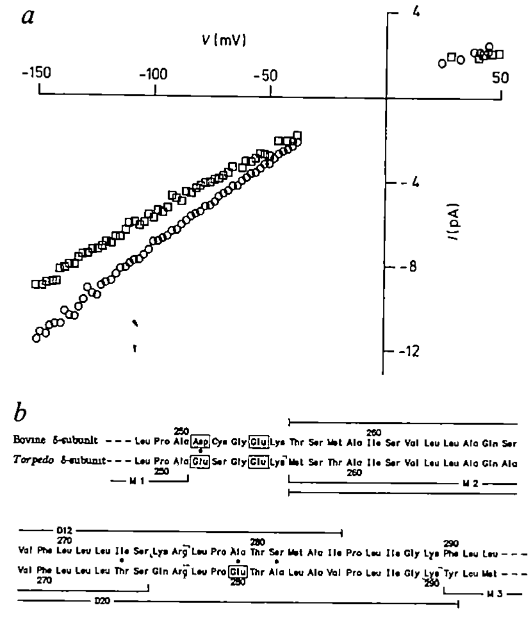

Fig 4 *a*, Single-channel *I*–*V* relations of the (□) AChR-D12 and (○) AChR-D20 channels Experimental details as in Fig 1*a*, pipettes filled with LDCS The slope conductances of the AChR-D12 and AChR-D20 channels shown are 65 pS ($r^2 = 0\ 994$) and 85 pS ($r^2 = 0\ 997$), respectively *b*, Comparison of the amino-acid sequences of the bovine (top) and *Torpedo* (bottom) AChR δ-subunits in the M2 and adjacent regions The bovine and *Torpedo* sequences are aligned[15] and the bovine sequence in the D12 subunit and the *Torpedo* sequence in the D20 subunit are indicated Asterisks, amino-acid differences between the two sequences, negatively charged and positively charged residues are enclosed with solid and dashed lines, respectively Amino-acid numbers[15 21] are given and the positions of segments M1, M2 and M3 are indicated, note that the amino-acid numbers of the two δ-subunits do not coincide with the alignment because of a gap present upstream

the *Torpedo* β-, γ- and δ-subunit-specific mRNAs (α-hybrid AChR, ref 4) or with the bovine δ-subunit-specific mRNA and the *Torpedo* α-, β- and γ-subunit-specific mRNAs (δ-hybrid AChR, ref 4) Figure 2 shows the single-channel *I*–*V* relations of the α-hybrid (round symbols) and δ-hybrid (square symbols) AChR channels in low divalent cation extracellular solution The K$^+$ conductance of the α-hybrid AChR channel is 86±2 pS (Fig 3*b*) This is similar to the conductance of the parental *Torpedo* AChR channel, suggesting that a difference in the α-subunit is not responsible for the larger conductance of the *Torpedo* AChR channel In contrast, the K$^+$ conductance of the δ-hybrid AChR channel is 65±2 pS (Fig 3*b*), being similar to that of the bovine AChR channel Thus, the difference in K$^+$ conductance between the *Torpedo* and bovine AChR channels can be ascribed, at least partly, to a difference in their δ-subunits The contributions of the β- and γ-subunits were not assessed because of the very low channel activities of the β-hybrid and γ-hybrid AChRs expressed in *Xenopus* oocytes[4]

To localize that part of the δ-subunit molecule responsible for the difference in the *Torpedo* and δ-hybrid AChR channel conductances, we prepared cDNA constructs encoding chimaeric δ-subunits in which portions of the *Torpedo* δ-subunit were systematically replaced by homologous regions of the bovine δ-subunit (Fig 3*a*) The mRNA derived from each of these cDNA templates, together with the *Torpedo* α-, β- and γ-subunit-specific mRNAs, was injected into *Xenopus* oocytes to produce AChRs with the different chimaeric δ-subunits Figure 3*b* shows graphically the K$^+$ conductances, measured in low divalent cation solution, of these AChR channels with the different chimaeric δ-subunits The conductances observed fall into one of two broad classes of lower, bovine-like (64–72 pS) or higher, *Torpedo*-like (85–88 pS) mean conductance

The conductance of the AChR-D1 channel (86±2 pS) and that of the AChR-D2 channel (72±3 pS) suggest that the portion of the δ-subunit comprising the amino-terminal extracellular region and the putative transmembrane segments M1, M2 and M3 (refs 10–14) is responsible for the different K$^+$ conductances of the *Torpedo* and δ-hybrid AChR channels Comparison of the conductances of the AChR-D16 channel (86±2 pS) and the AChR-D6 channel (69±3 pS) further suggests that the critical region lies in the portion containing segments M2 and M3 To refine this mapping, we tested AChRs with δ-subunit chimaeras in which only small segments had been exchanged

The conductances of the AChR-D17 channel (86±3 pS) and the AChR-D8 channel (71±2 pS) are in agreement with the above localization Furthermore, the conductances of the AChR-D9, AChR-D10 and AChR-D11 channels (64±4 pS, 85±1 pS and 85±1 pS, respectively) exclude a major involvement of segment M3 as well as of segment M1 Finally, the conductance of the AChR-D12 channel (67±3 pS), in which only the segment composed of amino-acid residues 256–284 of the bovine δ-subunit[15] has been substituted for the *Torpedo* sequence, is similar to that of the δ-hybrid AChR channel (see Fig 4*a*, square symbols and Fig 4*b*) In accord with this result is the conductance of the AChR-D20 channel (88±3 pS), which is similar to that of the *Torpedo* AChR channel (see Fig 4*a*, round symbols) The D20 subunit is nearly a 'mirror image' of the D12 subunit in that only the segment composed of amino-acid residues 256–290 of the bovine δ-subunit has been replaced by the *Torpedo* sequence (Fig 4*b*) The AChR-D12 and the AChR-D20 channel showed a Ca^{2+} dependence of their conductance similar to that of the bovine and the *Torpedo* AChR channel, respectively

From these results, we conclude that the region of the δ-subunit comprising segment M2 and the adjacent bend portion between segments M2 and M3 is principally responsible for the difference in K$^+$ conductance between the *Torpedo* and bovine AChR channels In line with this conclusion is the finding that replacement of the *Torpedo* α-subunit by the bovine α-subunit, both of which contain an identical amino-acid sequence in this region, does not alter the channel conductance Thus, our results suggest that the M2 and bend region represents an important determinant of the rate of ion transport through the AChR channel Recently it has been reported that segment M2 contributes to the binding site of noncompetitive antagonists[16–18]

In the bend portion between the putative transmembrane segments M2 and M3, the *Torpedo* δ-subunit has one negative and one positive charge, whereas the bovine δ-subunit has two positive charges, the lysine residue immediately preceding segment M3 is not taken into account because the five amino-acid residues preceding segment M3 are common to the two δ-subunits (Fig 4*b*) All subunits of both the *Torpedo* and bovine AChRs contain negatively charged residues in this bend portion[10,15], except the bovine δ-subunit A hypothesis consistent with our results is that the negatively charged residues in the bend portion of the AChR subunits are located near the mouth of the channel, attracting permeant cations toward the channel One effect of substituting the D12 chimaeric subunit for the *Torpedo* δ-subunit would be to reduce the number of negative charges in the mouth region Alternatively, the M2 and bend region may constitute part of the channel wall and its amino-acid sequence may partly determine the energy profile experienced by permeating cations in the channel

We thank Drs S DeRiemer, F Conti and E Neher for reading the manuscript This investigation was supported in part by the Ministry of Education, Science and Culture of Japan, the Mitsubishi Foundation and the Japanese Foundation of Metabolism and Diseases

The study of human autoimmune diseases has benefited greatly from analysis of animal models. Mice that are homozygous for either the *lpr* (lymphoproliferation)[1] or *gld* (generalized lymphoproliferative disease)[2] mutant genes develop a disease characterized by massive lymphadenopathy and autoantibody formation. With age, the lymphoid organs in these mice are replaced with a greatly expanded population of abnormal lymphocytes[3–5]. Recent work has shown that these cells are likely to be in the T-cell lineage. They rearrange and transcribe the genes for the α and β subunits of the T-cell receptor (TCR) and a third, T-cell receptor-like gene, T_γ[6,7] As determined by immunofluorescence with anti-receptor antibodies the cells also express TCR on the cell surface. The murine T-cell receptor consists of the α and β chains, derived from the rearranged α and β genes, in non-covalent association with seven other chains; the δ chain, of relative molecular mass (M_r) 26,000 (26K), the ε chain (25K), a glycosylated 21K chain (gp21) which is probably the homologue of the γ chain of T3 (CD3), a 16K homodimer (ζ) and a 21K dimer (p21)[8–10]. This multichain complex is thought to be the murine analogue of the human T3 complex. After activation of normal T cells by antigen or lectin, p21 is phosphorylated on tyrosine residues and gp21 is phosphorylated on serine residues. In contrast, in the *gld* and *lpr* cells, p21 is phosphorylated even in the absence of antigen or lectin, whereas gp21 is not phosphorylated.

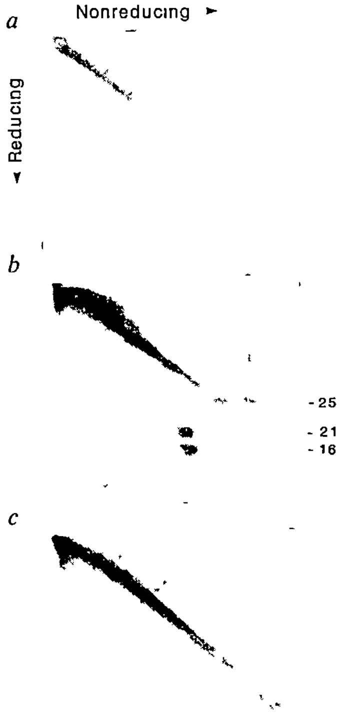

Fig 1 Two-dimensional diagonal SDS-polyacrylamide gel electrophoresis (PAGE) of phosphorylated normal and *lpr* T cell antigen receptors Purified Ly2⁻, L3T4⁻, lymph node cells lacking surface immunoglobulin from C3H-*lpr* animals (*a*, *b*) and purified T cells from normal C3H spleens and lymph nodes (*c*) were ^{32}P-labelled and solubilized in 0 5% Triton X-100 Immunoprecipitations were performed with preimmune rabbit serum (*a*) or with rabbit anti-δ chain serum[9] (*b*, *c*)

Methods The abnormal C3H-*lpr* and *gld* T cells (L3T4$^-$, Ly2$^-$) were separated from normal L3T4$^+$ and Ly-2$^+$ T cells by panning as described[7] C3H +/+ T cells were isolated from a mixture of spleen and lymph node cells by incubating 5×10^7 cells on anti-immunoglobulin coated plates for 45 min at 20 °C as described previously[7] Surface-immunoglobulin-negative cells were recovered by gently washing the plates five times After concentration by centrifugation the cells were applied to a fresh set of anti-Ig coated plates for a second cycle of purification The cells were washed in phosphate-free RPMI1640, resuspended in this medium with 10% dialysed fetal calf serum at $2 4\times10^7$ cells per ml and incubated with 0 8 mCi ml^{-1} [^{32}P]orthophosphate for 1 h at 37 °C The cells were then washed and solubilized as previously described[10] Immunoprecipitations were performed with 20 μl of preimmune serum or anti-δ serum adsorbed to protein A-Sepharose The immunoprecipitates were washed and eluted as described[10] The eluents were electrophoresed in the first dimension (left to right) without reduction in a 13% SDS-PAGE tube gel The tubes were equilibrated in 0 5% dithiothreitol, 0 1% SDS, 0 125 M Tris *p*H 6 8 for 2 h at room temperature before electrophoresis in a 13% SDS-PAGE slab gel in the second dimension Gels were treated and autoradiographed as described[10] Each panel represents immunoprecipitation of lysates from 6×10^7 cells Molecular weight markers are shown The gel was exposed to film for 48 h at −70 °C

The autosomal recessive mutations *lpr* and *gld* are non-allelic genes, yet the abnormal cells that populate the lymph nodes of mice homozygous for either mutation are indistinguishable by a wide variety of criteria We have suggested that the mutations may affect different components of a common metabolic pathway of major importance to T-cell differentiation and function[4] The abnormal cells of *lpr* and *gld* mice appear to express a normal complement of clonally determined α-β heterodimers at the cell surface but fail to respond to simulation with alloantigens[7], raising the possibility that the T-cell receptor is involved in the mutation Therefore, the antigen receptors on the abnormal T cells of *lpr* and *gld* mice were isolated and compared to those of normal peripheral T cells The cells were purified by plate separation techniques, surface radio-iodinated and solubilized in non-ionic detergents The antigen receptors were isolated with an antibody that binds the murine antigen receptor δ chain and is capable of immunoprecipitating the entire complex[9] All the components of the receptor are specifically co-immunoprecipitated with the anti-δ chain reagent from both

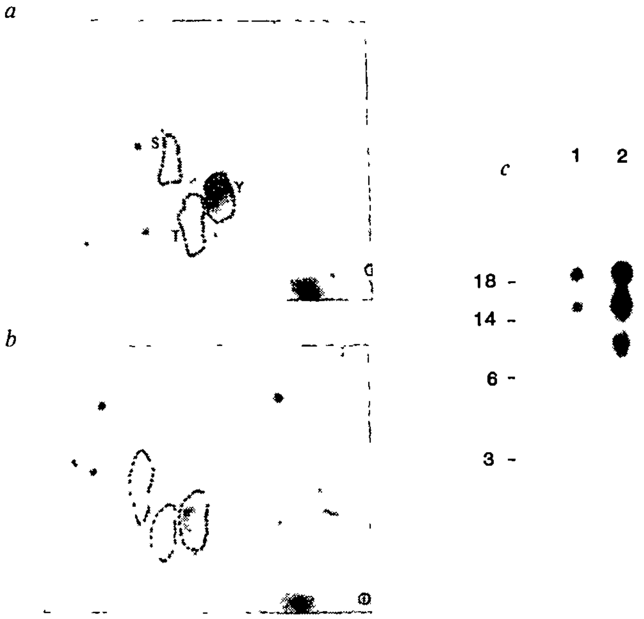

Fig 2 *a*, *b*, Phosphoamino acid analysis of phosphorylated antigen receptor subunits from abnormal *gld* cells Phosphorylated 21K chains (*a*) or 16K chains (*b*) from C3H-*gld* cells were analysed (*c*) Phosphopeptide mapping of antigen receptor subunits by limited proteolysis Phosphorylated p21 subunits from antigen activated 2B4 cells (lane 1) and MRL/*lpr* cells (lane2) were subjected to limited proteolysis with staphylcoccal V8 protease

Methods Phosphoamino acid content of proteins was determined using a modification of the method of Cooper *et al*[17] The abnormal cells from C3H-*gld* and C3H-*lpr* lymph nodes were isolated, labeled with ^{32}P and solubilized as described in Fig 1 Labelled proteins were separated on two dimensional diagonal gels and detected by autoradiography as described in Fig 1 Gel regions containing individual proteins were excised and hydrolysed with 2 ml of 5 7 M HCl at 110 °C for 1 h After addition of 4 ml of water, the hydrolysates were centrifuged at 500*g* for 10 min, and the supernatants were lyophilized The residues were dissolved in 10 ml of water, to which was added Dowex AG1-X8 (400 μl of 50% v/v), and phosphoamino acid standards (1 μl of 1 mg ml^{-1} stock solutions) The *p*H of the solutions was adjusted to 7 5 to 8 5 with 10 mM NH$_4$OH Solutions were tumbled with the ion exchange resin at room temperature for 4 h and centrifuged The supernatant was reapplied to a second batch of resin and tumbled overnight The two sets of beads were washed with water and eluted with four sequential 0 5 ml applications of 0 1 M HCl Eluents were dried under vacuum, pooled in 1 ml of water, redried under vacuum, and stored at 4 °C Samples were mixed with phosphoamino acid standards and analysed by two dimensional high voltage electrophoresis on thin layer plates as described[16] Electrophoresis was performed at *p*H 1 9, at 900 V for 1 5 h in the first (vertical) dimension and at *p*H 3 5, at 900 V for 40 min in the second (horizontal) dimension Gels were exposed to film for 12 days The pigeon cytochrome *c* hybridoma 2B4 ($2\ 5\times10^8$) was ^{32}P labelled and activated as described elsewhere[11] The antigen receptor was isolated with the clonotypic monoclonal, A2B4-2[18] MRL/*lpr* cells (10^9) were phosphorylated and the antigen receptor was isolated as described in Fig 1 Phosphorylated components were isolated on two-dimensional diagonal gels, spots containing the p21 chains were cut out, and the polypeptides were subjected to proteolysis with V8 protease in the gel as described[19] A 15% acrylamide gel was used to resolve the phosphopeptides *a*, 48 h exposure, *b*, 16 h exposure

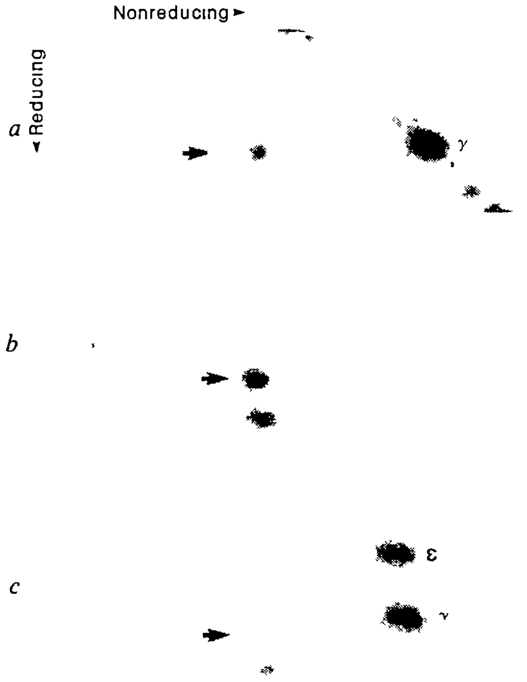

Fig 3 Two dimensional SDS-PAGE analysis of phosphorylated T cells Phosphorylated antigen receptors from *a*, antigen-activated 2B4 cells, *b*, C3H-*gld* cells, *c*, PMA treated C3H-*gld* cells were electrophoresed on 2D diagonal gels Arrow, phosphorylated p21 subunit

Methods The pigeon cytochrome *c* specific hybridoma 2B4 was ^{32}P-labelled and activated by antigen and the antigen receptor was isolated with the clonotypic monoclonal, A2B4-2 as described in Fig 2*a* C3H-*gld* cells were isolated as described in Fig 1*b*, *c* After phosphate labelling half of the *gld* cells were treated for 30 min with TPA at 100 ng ml^{-1} (*c*) Receptors from *gld* cells were isolated with the anti-δ chain antibody Electrophoresis and autoradiography were as described (Fig 1)

normal and abnormal T cell populations (data not shown) Several subunits of the T-cell antigen receptor are phosphorylated during T-cell activation[8,10-12] The 21K γ glycoprotein and, to a lesser degree, the 25K ε chain are phosphorylated on serine residues, and the p21 structure is phosphorylated on tyrosine residues within minutes of either antigen or mitogen presentation to T cell hybridomas Several other receptors are also phosphorylated on tyrosine upon activation, tyrosine phosphorylation is otherwise very rare[13] The serine phosphorylation is presumably due to the activation of protein kinase C and can be mimicked by the addition of TPA (tetradecanoyl phorbol 13-acetate) The kinase responsible for tyrosine phosphorylation has not been identified, but p21 phosphorylation is associated only with presentation of specific antigen or mitogenic lectin There is little, if any, phosphorylation of receptor chains without activation in normal cells Surprisingly, in contrast to normal T cells, the *lpr* (Fig 1) and *gld* T cell (Fig 3*b*) receptors were heavily phosphorylated in the absence of any added stimulus Labelled phosphates are added in the course of a one hour incubation This rapid turnover implies constitutive activation of both a kinase and a phosphatase Receptors isolated from T cells of animals with either mutation are constitutively phosphorylated on both 21 and 16K chains The 16K chain may be a proteolytic cleavage of the 21K chain but their exact relationship is still unclear As these bands are vertically aligned below the diagonal on this two dimensional gel, it is likely that they are linked under non-reducing conditions, they probably form a dimer in the receptor We have shown that specific antigen activation of T cell hybridomas results in phosphorylation of the p21 component of the antigen receptor on tyrosine residues[8,12], so we isolated the 21K and 16K proteins from the *gld* and *lpr* cells to determine which aminoacid was phosphorylated Both chains from the two mutant strains were phosphorylated on tyrosine (Fig 2*a*, *b*) Partial phosphopeptide mappings of p21 from *lpr* cells and an antigen-stimulated T-cell hybridoma with V8 protease (Fig 2*c*) and cyanogen bromide (not shown) are consistent with an identical site of phosphorylation The differences between the tyrosine phosphorylations on abnormal and normal T cells cannot be explained by enhanced phosphate exchange The turnover rate of the p21 tyrosine phosphate in *gld* cells is the same (~20 min) as that seen in activated normal T cells (data not shown) In normal T cells there is no tyrosine phosphorylation on p21 in the absence of stimulation The constitutive phosphorylation in the *gld* and *lpr* cells must be due to abnormalities in the tyrosine kinase pathway

In our previous studies, we found that whenever antigen or mitogen activates T cells, two parallel phosphorylation pathways are activated resulting in the serine phosphorylation of gp21 and the tyrosine phosphorylation of p21 A relatively fixed relationship between the intensities of these two phosphorylations is found over a wide range of antigen doses An example (Fig 3*a*) shows that the intensity of the serine phosphorylation is greater than that of tyrosine phosphorylated p21 in a T cell hybridoma Normal splenic T cells stimulated for 1 hour or 40 hours with the mitogen concanavalin A also show both serine and tyrosine phosphorylations (data not shown) The relative absence of the 16K phosphoprotein in the 2B4 cells appears to be peculiar to this hybridoma as mitogen-stimulated splenic T cells also show the 21K and 16K tyrosine-phosphorylated doublet In contrast, the *gld* (Fig 3*b*) and *lpr* (Fig 1*b*) cells demonstrate no detectable gp21 serine phosphorylation despite high levels of p21 tyrosine phosphorylation The addition of mitogens to *lpr* and *gld* cells failed to enhance the tyrosine phosphorylation and did not result in gp21 serine phosphorylation, again in contrast to normal T cells This is consistent with the failure to proliferate in response to stimulation with concanavalin A We examined whether the absence of gp21 serine phosphorylation was due to lack of activatable protein kinase C Addition of TPA to normal T cells or T-cell hybridomas bypasses the receptor and directly activates this kinase resulting in serine, but not tyrosine phosphorylation of antigen receptor subunits We therefore added TPA to ^{32}P-labelled *gld* cells (Fig 3*c*) This results in the expected gp21 phosphorylation and enhanced ε phosphorylation indicating that protein kinase C is both present and capable of phosphorylating the *gld* gp21 subunit Interestingly, TPA treatment seems to inhibit phosphorylation of p21

The constitutive tyrosine phosphorylation in the absence of serine phosphorylation distinguishes the abnormal cells of *gld* and *lpr* from bulk populations of resting splenic T cells, mitogen activated T-cell blasts or antigen-activated T-cell hybridomas, but the fact that the abnormal T cells in these disorders are phenotypically different from the T cells to which they were compared makes the interpretation of these differences difficult We do not know whether the T cells in these animals are aberrant lineages unique to the disease, or an abnormal expansion of a rare T cells subset present in normal animals If these cells do exist in normal mice, they might show the same phosphorylation phenomena reported here The recent report of 'double negative' T cells in the periphery of normal individuals may be due to just such populations[13,14] The fact that the T cell antigen receptor plays such a crucial role in the growth and differentiation of T cells makes understanding its function in abnormal T cells essential The observation that a biochemical pathway identified with receptor activation is constitutively activated in these abnormal T cells may offer clues to the pathogenesis of the disease processes A defect in the coupling mechanism between the receptor and kinase, or abnormalities in intracellular kinase regulation may be the manifestation of the mutant genes The clear role of tyrosine kinases in both normal and abnormal growth and differentiation suggests parallels to this system Current views about the *erb*B oncogene, for example, postulate that its transforming activity is due to the functioning of a constitutively active tyrosine kinase no longer under the regulation of a growth factor hormone[15,16] Two observations reported here suggest a similar dissociation from normal ligand regulation (1) the constitutive tyrosine phosphorylation in the absence of any apparent ligand, and (2) the lack of receptor serine phosphorylation that characterizes normal ligand induced receptor-activation Pursuing the implications and consequences of these unusual phosphorylations may elucidate mechanisms involved in both normal and abnormal T cell function

We thank H Luong for technical assistance and K Perry for preparation of the manuscript

Polymorphism of human Ia antigens generated by reciprocal intergenic exchange between two DR β loci

Shaokee Wu, Thomas L. Saunders & Fritz H. Bach

Immunobiology Research Center, Box 724 Mayo Memorial Building,
University of Minnesota, Minneapolis, Minnesota 55455, USA

Class II molecules encoded by the human major histocompatibility complex (MHC) are involved in regulating T-cell response to antigens[1–3]. The mechanisms for generating polymorphism in products of the MHC have been studied extensively for both the murine H–2 and the human HLA complex. Such studies indicate that point mutations plus selection have a major role in the generation of polymorphisms of class I and class II MHC genes[4–8]. However, a non-reciprocal gene conversion mechanism has been proposed to explain several examples of clustered sequence variation in MHC genes[9–14]. In all these examples, the proposed gene conversion event is unidirectional; that is, one of the two interacting genes acts as sequence donor and the other as sequence recipient. No examples of potential reciprocal genetic exchange (as occurs in the fungal system[15,16]), in which the two interacting genes act as both donor and recipient of gene fragments, have been found in the MHC system or in other multigene families of higher organisms. We sequenced two different HLA-DR β complementary DNAs from each of two different cells all expressing the same serologically defined determinant (DR2) but different T-cell-recognized (Dw) specificities (Dw12 and MN2). Sequence comparisons of these four cDNA clones (and two DR β amino-acid sequences from the DR2–Dw2 subtype) suggest that new coding sequences for DR β molecules in the DR2 haplotypes are potentially generated by reciprocal intergenic exchange

Table 1 lists six amino-acid sequences for DR β genes from three different DR2 subtypes (DR2-Dw2, DR2-Dw12 and DR2-MN2)[17] (For simplicity only amino acids that differ between any two sequences are given, see ref 18 for a complete listing

Table 1 Grouping and comparison of amino-acid sequences of six DR β-chains from HLA-DR2 individuals

			Amino-acid position																													
			First domain														Second domain											CP	TM		CY

	MN2-61	MN2	R	W	P	R	D	Y	F	S	V	Y	F	D	R	V	G	Q	S	K	P	Q	S	L	G	M	N	T	R	V	R	Q

The table lists differences in the amino-acid sequences of six DR β-chains from three different HLA-DR2-positive individuals Positions not shown in the table are identical in all six DR β-chains (see ref 18 for a complete listing of shared amino-acid residues) The Dw2-A and Dw2-B sequences are from protein sequencing of two DR β-chains of a DR2-Dw2 homozygous cell line[18] The other four sequences are deduced from cDNA clones obtained from cDNA libraries constructed in our laboratory These four cDNAs encode DR β molecules as revealed by restriction mapping (especially characteristic internal *Pst*I sites) and comparison with available DR β sequences[6 7] DHO (DR2-Dw12) is a homozygous typing cell (HTC) line[17] The MN2-2 and MN2-61 sequences are from an individual typed as DR2-MN2/DR4-Dw4 MN2-2 and MN2-61 are considered to be DR β sequences from the MN2 haplotype because (1) their sequences are different from the two published DR β genes of the DR4-Dw4 haplotype[35 41], (2) they have greater homology to other DR2-derived DR β sequences than to DR4 DR β sequences, (3) we have sequenced another DR β_1 cDNA from the same cell line and found it to be identical to other DR4-DW4 DR β_1 sequences[35 41] (S W *et al*, unpublished observation) cDNA was synthesized using oligo(dT) to prime the first strand and nascent messenger RNA was nicked with RNase H to prime the second strand synthesis[22] cDNA was 'blunt-ended' with DNA polymerase and tailed with dCTP using terminal deoxynucleotidyl transferase cDNA was annealed with *Pst*I-cut, d*G*-tailed single-stranded plasmid vector pUC119 (ref 42) and introduced into *E coli* strain MV1193 Each library, which contained about 50,000 colonies, was screened with a 790-bp *Sct*I/*Hin*dIII fragment of a DR β cDNA clone[43] labelled with ^{32}P by nick translation This probe contains almost the entire coding region from this clone and under the hybridization conditions used, reacts most strongly with DR β cDNA but also reacts weakly with DQ β and DP β cDNAs The inserts were sequenced directly on pUC119 or truncated subclones were generated by the method of Dale *et al*[44] The second orientation was sequenced from inserts subcloned into plasmid vector pUC118 or M13 mp18 Sequencing was done in both orientations using the dideoxy chain termination method[45] with the M13 universal sequencing primer[46] or oligonucleotide primers corresponding to conserved DR β sequences The DHO-7 clone contains a truncated insert The available sequence of DHO-7 starts at amino-acid[45] Amino-acid residues of interest are boxed Residues not available for comparison are marked with a dash CP refers to the connecting peptide, TM to the transmembrane region and CY to the cytoplasmic tail of the DR β molecule The total length of the DR β-chain, not including the signal peptide, comprises 237 amino acids

Table 2 χ-Like sequences in the immunoglobulin–MHC supergene family

Species	Gene	Altered nucleotide/consecutive nucleotides*	χ-Like sequence	Refs
Murine	MHC-class II A_β^{bm12}	3/14	GCTGGGG	11, 12
Murine	MHC-class I K^{bm1}	7/13	GCTGGTG	9, 10
Human	MHC-class II DR3-DRβI	7/34	GCTGGGG	14
Human	MHC-class II DR2-DR β	7/18	GCTGGGG	This paper
Human	MHC-class I B27k	4/14	GCTGGTG	13
Murine	IgD V gene	15/164	GCCTGGGG(CTGA)GCTGGTG(AA)GCCTGGGG	32

The χ sequence is GCTGGTGG or its complement or its duplex[26] The χ-like sequence for the immunoglobulin switch region is GCTGGTG(G) (ref 28), for Ti-plasmid GCTGGTGG and GCTGTTGG (ref 29), for a core sequence in human 'minisatellite' DNAs GGAGGTGGGCAGGA$^{A}_{G}$G (ref 30), and for murine class II E_β gene $(GGCA)_{25-37}$ (L Hood, personal communication)

* The number of altered nucleotides/the number of consecutive nucleotides from the first to last alteration

of shared amino-acid residues) The six sequences can be classified unambiguously into two groups by sequence homology, they presumably represent the two expressed DR β molecules in the DR2 haplotype[19,20] The group I DR β molecules are apparently more polymorphic than the group II DR β molecules Of greatest importance are amino acids 67–71 (Table 1) These five residues are shared by MN2-2 in group I and two sequences in group II (Dw2-B and DHO-8), also, MN2-61 in group II shares these five residues with two sequences in group I (Dw2-A and DHO-7) Corresponding cDNA nucleotide sequences of these DR β molecules (Fig 1) show that DHO-7 (group I) and MN2-61 (group II) share all 18 nucleotides coding for residues 67–72, as do DHO-8 (group II) and MN2-2 (group I) These two 18-nucleotide sequences differ at 7 positions, resulting in 3 amino-acid substitutions out of 6 It is extremely unlikely that seven nucleotide differences are due simply to the accumulation of sequential point mutations[21], especially as the third base of each codon is the same for each amino acid The simplest explanation of this finding is that there has been reciprocal genetic exchange of this segment between the two non-allelic expressed DR β genes

The non-reciprocal gene conversion events implicated in generating the A_β^{bm12} allele (murine)[11,12], DR3 haplotype (human)[14] and various DR4-Dw subtypes[14,22,23] involve the same third hypervariable region in the first domain of the class II gene This hypervariable region apparently specifies an epitope for alloreactivity[11,22–24] and restricted recognition[25] The finding that this functionally important segment of the class II gene is frequently involved in gene conversion-like events prompted us to look for a unique sequence which may promote genetic recombination[15,16 26,27] These include the χ sequence in λ phage and *Escherichia coli* (5'-GCTGGTGG-3' or its complement or its duplex)[26] and the repeated T G and C G dinucleotides implicated in a gene conversion event in the human globin genes[27]

χ-Like sequences have been recognized in DNA which undergo rearrangement or recombination (refs 28–30 and L Hood, personal communication) (Table 2) A χ-like sequence (5'-GCTGGGG-3') is found 36 base pairs (bp) upstream from the 18-bp 'interconverted' hypervariable segment within a region of complete sequence homology from amino-acid residue 48 to 66 among all four DR β cDNAs that we have sequenced (from the second exon) (Fig 1) The amino-acid sequences for Dw2-A and Dw2-B (ref 18) (Table 1) are consistent with such a nucleotide sequence

There are two other χ-like sequences in the DR2 β cDNAs, one near amino acid 1 (from the first exon) (Fig 1) and another near residue 140 (5'-GCTGGGG-3' for both MN2-2 and DHO-7, and 5'-GCTGGGA-3' for both MN2-61 and DHO-8, these

Fig 1 Nucleotide sequences of four cDNA clones encoding HLA-DR β molecules from two different HLA-DR2 subtypes The sequences shown include the leader sequence (from residue −29 to −1) and the first domain (residues 1-94) DHO-7 and DHO-8 cDNAs are from DR2-Dw12, and MN2-2 and MN2-61 from DR2-MN2 The deduced amino-acid sequence for the DR β cDNA clone MN2-61 is given above the MN2-61 nucleotide sequence Dashes in the sequences indicate identity with the MN2-61 sequence Numbers correspond to the amino-acid sequence of the DR β molecule with a leader sequence 29 amino acids long The 5'-GCTGGGG-3' sequence is boxed due to its similarity to the χ sequence (5'-GCTGGTGG-3') of λ phage, a signal for generalized recombination in *E coli*[26]

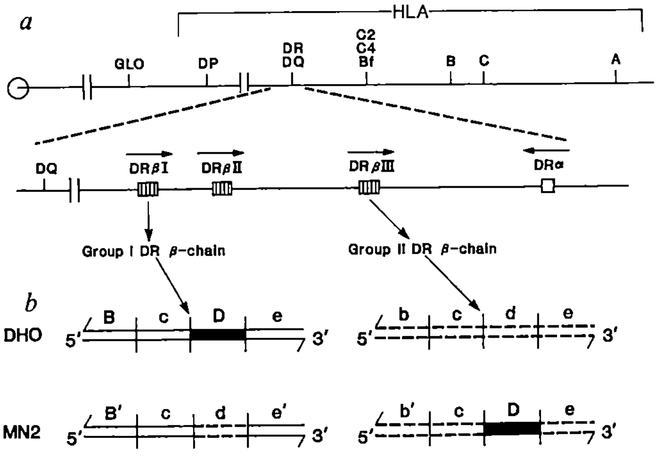

Fig 2 Genetic map of the human MHC[34,35,47] and schematic representation of the reciprocal genetic exchange in the second exon (first domain) of the non-allelic, expressed DR β genes *a*, The human MHC is located on the short arm of chromosome 6 The relative position of DP genes, DQ genes, the DR α gene and DR β genes on the map was determined by pulse-field electrophoresis mapping[47] and by genomic cloning and sequencing[34,35] The DRβII gene in both DR3 and DR4 haplotypes is a pseudogene[34,38] It remains to be proven whether the HLA-DR2 haplotype also has a DR β pseudogene In this figure we suggest that the DRβI gene encodes the more polymorphic group I DR β molecules (Table 1) and that the DRβIII gene encodes the less polymorphic group II DR β molecules (Table 1), as in the DR3 and DR4 (refs 14, 35) haplotypes, but this remains to be conclusively demonstrated by genomic and/or amino-acid sequencing The circle represents the centromere, and arrows show the direction of transcription[34,35] *b*, For ease of illustration, the second exon (amino acids 5-94) of the DR β gene is divided into four segments B/b amino acids 5-47, c, 48-66, D/d, 67-72, and e, 73-94 B/B'/b/b', D/d, e/e' indicate sequence variation in that particular segment between alleles and/or loci Identical letters indicate sequence identity The χ-like sequence 5'-GCTGGGG-3' is found in the conserved c segment The D/d segment is the minimum 18-nucleotide sequence being potentially interconverted See Table 1 for amino-acid sequences and Fig 1 for nucleotide sequences

sequences are from the third exon) We also identified χ-like sequences in published sequences of other class I and class II MHC genes as well as immunoglobulin genes (which belong to the same supergene family as the MHC genes[31]) where gene conversion-like events have been proposed[9-14,32] (Table 2) The frequent observations of χ-like sequences upstream from the potentially 'converted' gene segments suggest that χ-like sequences may be associated with recombination hot spots involved in a gene conversion-like event in the immunoglobulin-MHC supergene family Promotion of recombination by χ-like sequences may be tested by using tetrad analysis of yeast recombination system[33]

The DR genomic organization of the DR2 haplotype is not known If we assume that it is similar to that of the DR3 (ref 34) and DR4 (ref 35) haplotypes (Fig 2*a*), the genetic events which lead to the formation of current DR β genes in different DR2 subtypes may be postulated as follows (1) gene duplication and deletion from a primordial gene of the immunoglobulin supergene family[7,31] to generate one DR α gene and three DR β genes (Fig 2*a*), (2) point mutations generating DR β gene polymorphism including the 18 bases encoding residues 67-72, (3) genetic interactions and recombination between two non-allelic DR β loci (probably the DRβI and DRβIII genes), leading to the exchange of residues 67-72 (Fig 2*b*) and (4) further point mutations Whether the third DR β gene (DRβII, which may or may not be a pseudogene for the DR2 haplotype) is involved in the recombination process is unknown

To explain the genetic interactions and recombination, we hypothesize that the intergenic exchange was initiated by the χ-like sequence and involved the two non-allelic DRβI and DRβIII genes on the same chromatid looping back on itself in a single genetic event with the reciprocal exchange of gene segments[36,37] Our model would be equally applicable if exchange occurred between sister chromatids or between chromosomes that have a high degree of sequence homology and carry the two 18-nucleotide sequences encoding residues 67-72 (Fig 2) However, we do not exclude the possibility that reciprocal intergenic exchange resulted from two temporally independent non-reciprocal gene conversion events, or that double crossing-over can account for our observation, given the fact that 24-74 bp of complete sequence homology are sufficient for genetic recombination (segments c and e in Figs 1 and 2)[38-40], although this is less likely given interference between closely linked genetic markers in crossing over

Gene conversion and reciprocal intergenic exchanges in MHC genes frequently involve hypervariable regions specifying functional epitopes and may allow the re-shuffling of functionally important epitopes to increase the combinatorial usage of a limited number of hypervariable regions and to create novel H-2 and HLA haplotypes

Predominant use of a V_α gene segment in mouse T-cell receptors for cytochrome *c*

Astar Winoto*, James L. Urban, Nancy C. Lan, Joan Goverman, Leroy Hood & Daniel Hansburg†

The T-cell receptor is a cell surface heterodimer consisting of an α and a β chain that binds foreign antigen in the context of a cell surface molecule encoded by the major histocompatibility complex (MHC), thus restricting the T-cell response to the surface of antigen presenting cells[1-4]. The variable (*V*) domain of the receptor binds antigen and MHC molecules and is composed of distinct regions encoded by separate gene elements—variable (V_α and V_β), diversity (D_β) and joining (J_α and J_β)—rearranged and joined during T-cell differentiation to generate contiguous V_α and V_β genes[5-11]. T-helper cells, which facilitate T and B cell responses, bind antigen in the context of a class II MHC molecule. The helper T-cell response to cytochrome *c* in mice is a well-defined model for studying the T-cell response to restricted antigen and MHC determinants. Only mice expressing certain class II molecules can respond to this antigen ($E^k_\alpha E^k_\beta$, $E^k_\alpha E^b_\beta$, $E^v_\alpha E^v_\beta$ and $E^k_\alpha E^s_\beta$)[12-14]. Most T cells appear to recognize the C-terminal peptide of cytochrome *c* (residues 81–104 in pigeon cytochrome *c*)[15-18]. We have raised helper T cells to pigeon cytochrome *c* or its C-terminal peptide analogues in four different MHC congenic strains of mice encoding each of the four responding class II molecules. We have isolated and sequenced seven V_α genes and six V_β genes and analysed seven additional helper T cells by Northern blot to compare the structure of the V_α and V_β gene segments with their antigen and MHC specificities. We have added five examples taken from the literature[19-22]. These data show that a single V_α gene segment is responsible for a large part of the response of mice to cytochrome *c* but there is no simple correlation of MHC restriction with gene segment use.

The junctional nucleotide sequences for the V_α and V_β genes are given in Figs 1 and 2, respectively, and data for all the T cells examined are summarized in Table 1 These data, with functional studies to be discussed subsequently, demonstrate several interesting points

The $V_\alpha 11$ 1 gene segment is the one most often used in the mouse helper T-cell response to cytochrome *c* (14 out of 19 T_H cells) The closely related $V_\alpha 11$ 2 gene segment (eight nucleotide substitutions out of 312) is used in the 15th T_H cell The other predominant gene segments are used far less frequently than $V_\alpha 11$ 1 ($J_\alpha 84$, 6 of 12, $V_\beta 3$, 7 of 19, $J_\beta 1$ 2, 7 of 12) Some of

*C F6, 5C C7, B10 and 4 C3 are cloned helper T-cell lines induced in B10 A mice immunized with pigeon cytochrome *c*[22] The rest of the cells are T-helper hybridomas generated as described[46] 2B4 has been reported previously[19 20] Hybridomas were made by fusing BW5147 lymphoma cells with cytochrome *c*-specific T-cell lines induced in four different congenic mouse strains B10 A ($E^k_\alpha E^k_\beta$, AN and BC hybridomas), B10 SM ($E^v_\alpha E^v_\beta$, AR hybridomas), B10 A (5R) ($E^k_\alpha E^b_\beta$; V hybridomas) and B10 S (9R) ($E^k_\alpha E^s_\beta$, AP hybridomas) The mice were immunized with either pigeon cytochrome *c* (2B4 and BC hybridomas) or synthetic C-terminal homologous peptides to cytochrome *c* Sp (AN hydridomas) or DASp (V, AP, AR hybridomas)[46] B10 A and B10A(5R) hybridomas respond to antigen presented on $E^k_\alpha E^k_\beta$ or $E^k_\alpha E^b_\beta$ antigen presenting cells (APC) and B10 S(9R) and B10 SM hybridomas respond to antigen on $E^k_\alpha E^s_\beta$ or $E^v_\alpha E^v_\beta$ APC[12]

† Gene segment use was determined by DNA sequence analysis (for methods see legend of Fig 1) unless otherwise indicated Nomenclature is essentially as described[21-23] with the exception of J_α14 4 and J_α11 2 which have not been reported previously (for sequence see legend of Fig 1) The two distinct members of the V_α11 subfamily are denoted V_α11 1 and V_α11 2, these two members have been previously referred to as V_α2B4 2 and V_α2B4 1, respectively[22] They differ by only eight nucleotides in the coding region and nine nucleotides in the 5′ flanking region (ref 22 and data not shown) The V_α gene of hybridoma AP11 2 is denoted V_α4 3 to distinguish it from the two published V_α sequences belonging to the V_α4 subfamily[23] V_β3 has also been referred to as V_β2B4[22]

‡ Boxes indicate predominant gene segment use

§ Determined by Northern blotting using gene segments from V1 9 2 and AP11 2 as probes Use of V_α11 1 by AR8 1 was determined by additional Southern genomic blotting using a V_α11 flanking region probe V_α other than V_α4 and V_α11 are denoted by 'X'

# Determined by Northern blotting using probes from the V_β2,3,4,5,8 and 14 subfamilies V_β other than those used as probes denoted by 'Y'

The J_α11.2 sequence is

CTGGAGGCTATAAAGTGGTCTTTGGAAGTGGGACTCGA
TTGCTGGTAAGCCCTG

V and *J* region boundaries were determined by comparison to the germline sequences of V_α11 1 (ref 22), J_α84 (ref 47) and J_α28 (A W, unpublished data) and to the TA37 cDNA sequence (J_α37, ref 23) Nucleotides which could not be assigned to either *V* or J gene segments are designated 'N or D' and represent either additional non-germline sequences (*) or could not be evaluated because germline sequences are not known (+) Dots indicate identity to the B10 sequence

Methods The V_α genes of T-cell clones C F6, B10, 4 C3 and 5C C7 (ref 22) and of hybridoma 2B4 (refs 19, 20) were isolated from complementary DNA libraries as described The V_α genes of hybridomas V1 9 2, V11 5 and AP11 2 were isolated from λgt10 cDNA libraries and subcloned into m13mp8 The rest of the hybridomas were isolated from limited genomic libraries constructed in λL47 1 or EMBL3 vectors and were subcloned into M13 mp18 and/or 19 Both strands of DNA were sequenced using the dideoxy chain termination method[48] with the M13 universal primer and a C_α-specific oligonucleotide (CA3) primer for the cDNA clones, and specific oligonucleotide primers for the genomic clones

this apparent degeneracy may reflect the diversity of antigens and/or MHC molecules used in immunization[22] (see Table 1), but the V_α11 1 protein sequence is clearly highly favoured in the construction of a specific antigen binding site for cytochrome *c*

Some nucleotides in the V_α junctional region are not encoded by either germline V_α or J_α gene segments (Fig 1) Comparison of the known germline J_α84 and J_α28 sequences with those given in Fig 1 allows us to determine where these J_α sequences end in the 5′ direction Although the germline sequence of V_α11 1 is not known, clearly four of the five different sequences denoted by asterisks in Fig 1 must represent extra nucleotides (the fifth could be the germline V_α11 1 sequence) Two explanations are possible First, the extra nucleotides could represent contributions from D_α gene segments This explanation seems unlikely because the number of added nucleotides is small (1-4) and no other evidence for D_α gene segments has yet been reported[23] The second possibility is that N-region diversification, the addition of random nucleotides in the junctional region to either of the joined gene segments[24,25], may occur It has been proposed that N-region diversification is caused by the enzyme terminal deoxynucleotidyltransferase (TdT)[26], which is present in T cells

Fig 2. V_β junctional nucleotide sequences of T-cell receptors recognizing cytochrome *c* Sequences of the C F6, B10, 4 C3, 5C C7 T-cell clones[22] and 2B4 (refs 19, 20) and V1 9 2 (refs 19, 21) hybridomas have been reported previously and are included for comparison Only nucleotides in and around the diversity (*D*) gene segment are shown, *V* and *J* sequences both up- and downstream of this region were found to be identical to those published previously[5,19,21,49] *V*, *D* and *J* region boundaries were determined by comparison to known germline sequences ($V_\beta3$ (ref 19), $D_\beta1$ 1 (refs 31, 32), $J_\beta1$ 1, 1 2 and 1 4 (ref 5), $J_\beta2$ 1 and 2 5 (refs 5,19)) and to the cDNA sequences of BW5147 ($V_\beta1$, ref 21), 86T1 ($V_\beta1$, ref 49) and TB23 ($V_\beta8$ 3, ref 21) Dots, identity to the AP11 2 sequence or to the $D_\beta1$ 1 sequence The T nucleotide in the *D* segment of 2B4 (*) corresponds to the T at position 6 of $D_\beta2$ 1 (GGGAC*T*GGGGGGGC, refs 31, 32)

Methods The V_β genes of T-cell clones C F6, B10, 4 C3 and 5C C7 (ref 22) and hybridomas 2B4 (refs 19, 20) and V1 9 2 (refs 19, 21) were isolated from cDNA libraries as described The other V_β genes were isolated from limited genomic libraries constructed in the λL47 1, EMBL3, λgt7*lac5* or λ590 vectors and sequenced in the same manner as the V_α genes

during early development at the time of rearrangement of the T-cell receptor genes[27-30] In contrast, N-region diversification is never seen in immunoglobulin light chains[24,25], which also lack *D* gene segments, presumably because TdT is not present in these cells when the gene segments are rearranged TdT shows a clear preference for the addition of G residues[21] and three out of five of the asterisked sequences in Fig 1 contain G as their sole or predominant nucleotide Although no conclusions can be reached about the five sequences denoted in Fig 1 as '+' because we do not have the corresponding germline V_α and/or J_α gene segment sequences, N-region diversification may add up to 15 bases in the joining process[24,25] The two remaining unmarked sequences in Fig 1 can be totally accounted for on the basis of germline sequence and thus represent 'error-free' *V–J* joining This agrees with the suggestion[19] that the use of N-region diversification or the joining of a D_α gene segment is not required for productive recombination

It is striking that all the rearranged V_α and V_β genes are different in sequence except for V_α AN6 2 and V_α V11 5 This enormous variability arises through (1) use of a multiplicity of distinct gene segments, (2) joining these gene segments in different combinations and (3) diversity of junctional regions arising because of N-region diversification or the flexibility in the regions at which the gene segments are joined There is extensive junctional flexibility in the V_α and V_β genes and N-region diversification in the V_β genes[31,32] (Figs 1 and 2) This variability emphasizes the fact that striking diversity in the third hypervariable region is compatible with T-cell receptor specificity for particular antigen-MHC determinants

There is no simple correlation between class II MHC restriction and T-cell receptor gene segment usage (Table 1) For example, in helper T cells raised in $E^k_\alpha E^k_\beta$ mice, the most frequently studied haplotype, three different V_α (11 1, 11 2, and X), three different J_α (84, 14 4 and 2B4), five different V_β (3, 14, B10, 8 and Y) and three different J_β (1 2, 2 1 and 2 5) gene segments are used Moreover, the $V_\alpha11$ 1 gene segment is used by all four haplotypes studied, and the $V_\beta8$ and $V_\beta3$ gene segments are present in three of these four haplotypes The enormous diversity observed in the junctional regions of α and β chains suggests that there are many different ways to select the T-cell receptor molecule for restriction to a particular MHC molecule

Analysis of the ten $V_\alpha11$ 1 gene segments reveals no nucleotide differences (Fig 1 and data not shown) Since all ten T-helper hybridomas are functional and presumably represent mature T cells, we conclude that somatic hypermutation occurs infrequently, if at all, in the α genes of T_H cells specific for cytochrome *c* Similar conclusions have been reached for the β genes of the T-cell receptor[9 21,33] and our data are consistent with this interpretation in that eleven V_β gene segments from three subfamilies are identical in their coding region nucleotide sequences to their subfamily members, except for one mutation at position 95 of the V11 5 V_β gene segment (Fig 2) Somatic hypermutation in B cells, essential for affinity maturation[34], appears to occur relatively late in B-cell differentiation[35-37] Our T cells were hybridomas generated from purified lymph node cells that were stimulated once *in vivo* and a week later placed in tissue culture with antigen for three days before fusion Thus the possibility that somatic hypermutation has not occurred because our T cells are analogous to primary B cells or because

Fig 3 Fine specificity of cytochrome *c* peptide-specific T hybridomas Hybridoma cells were cultured with varying concentrations of pigeon cytochrome *c* and B10 A ($E^k_\alpha E^k_\beta$) spleen cells as a source of antigen presenting cells After 40 h of culture, supernatants were transferred to the IL-2-dependent cell line HT-2 ^{3}H-thymidine was added to the secondary culture 16 h later Antigens were C-terminal peptides of pigeon or fly cytochrome *c*, or synthetic derivatives of the pigeon peptide[46,50] Note that an N-terminal cysteine has been added to the fly sequence A dash denotes identity, Δ denotes a deletion (compared with the pigeon sequence)

of the antigen excess condition *in vitro* cannot be excluded However, the data here and data from 27 human V_β sequences from peripheral blood[38] are consistent with the supposition that somatic hypermutation does not play an important role in generating the diversity of the T-cell receptor repertoire Hence, affinity maturation may not play any significant role in the T-cell recognition of antigen-MHC and the affinity of T-cell receptors for their cognate antigen may be generally lower than that of antibodies for their cognate antigen

The V_α and V_β chains from hybridomas AN6 2 and V11 5 are identical except for five amino-acid differences in the V_β hypervariable region formed by *V-D-J* joining (Fig 2) We studied the antigenic fine specificity of these hybridomas to six different related cytochrome *c* peptides (Fig 3) These two T cells responded differently to the panel of peptides For example, hybridoma V11 5 did not respond to the peptide DAK^{100} even at high levels of antigen concentration, whereas hybridoma AN6 2 reacted strongly with this peptide Although no MHC fine specificity data is available for these two T-cell clones, we know that both respond equally well to antigen presented on cells bearing $\mathrm{E}^k_\alpha\mathrm{E}^k_\beta$ or $\mathrm{E}^k_\alpha\mathrm{E}^b_\beta$ MHC molecules and not to cells bearing $\mathrm{E}^k_\alpha\mathrm{E}^s_\beta$ or $\mathrm{E}^v_\alpha\mathrm{E}^v_\beta$ molecules We thus conclude that changes limited to the junctional region of the V_β sequence may alter the antigenic fine specificity of individual T cells without altering their predominant MHC specificity As this region seems to correspond to the third hypervariable segment of immunoglobulin V region sequences[21,33,39,40], we conclude that this region is very probably part of the antigen binding site—consistent with the supposition that the V regions of T-cell receptors and immunoglobulins fold in a similar manner.

Further fine specificity studies on two other hybridomas using six different cytochrome *c* peptides resulted in a striking observation Hybridomas AN4 4 and AN14 4, which do not share the same pair of V_α and V_β gene segments, show nearly identical profiles of antigen fine specificity within the panel of peptides tested (Fig 3, pigeon cytochrome *c* > DASp peptide > fly cytochrome *c* > Sp peptide > DAK^{100} peptide > DAE^{100} peptide) The fact that two hybridomas which are similar in their antigen fine specificity and predominantly restricted to $\mathrm{E}^k_\alpha\mathrm{E}^k_\beta$ do not share the same pair of V_α and V_β gene segments suggest that a combination of different V_α and V_β regions can form very similar antigen-MHC binding pockets, again consistent with the idea that affinity for cognate antigen may be relatively low

The V_α-restricted nature of the cytochrome *c* T-cell response raises interesting clinical possibilities Several animal models of human autoimmune diseases such as multiple sclerosis, rheumatoid arthritis and Hashimoto's thyroiditis provide strong evidence for the pathogenic involvement of T cells in the development of these autoimmune disorders[41-45] These models also indicate that T-cell responses responsible for these autoimmune diseases are directed against restricted antigen determinants These situations may be similar to the T-cell response against cytochrome *c* and raise the possibility that these autoimmune diseases may be associated with predominant usage of a particular T-cell receptor V_α (or V_β) gene segment Antibodies to these *V* gene segments might then have useful diagnostic or therapeutic possibilities

We thank Debra Maloney and Karyl Minard for technical assistance, Bertha Jones, Connie Katz and Cathy Elkins for preparation of the manuscript, and Drs Richard Barth, Patrick Concannon, Joan Kobori, Mitchell Kronenberg, Ulf Landegren and Nilabh Shastri for a critical reading of the manuscript This research was supported by the NIH (L H) and NIH grant-in-aid AI-20661 and CA-06927 (D H)

The mammalian X and Y chromosomes, in contrast to the autosomes, pair during male meiosis only near the telomeres. Alleles localized in this region can undergo reciprocal exchange during meiosis[1-4]. Because such sequences do not show strict sex-linked inheritance, they have been termed pseudoautosomal[5] In man, several DNA sequences have been described which show pseudoautosomal transmission and which are localized in the pairing region at the ends of the short arms of both the X and Y chromosomes (refs 6-9, and D. Page, unpublished results). We now show that the transgenic mouse strain, Mov-15, contains a single Moloney murine leukaemia virus (M-MuLV) genome in its

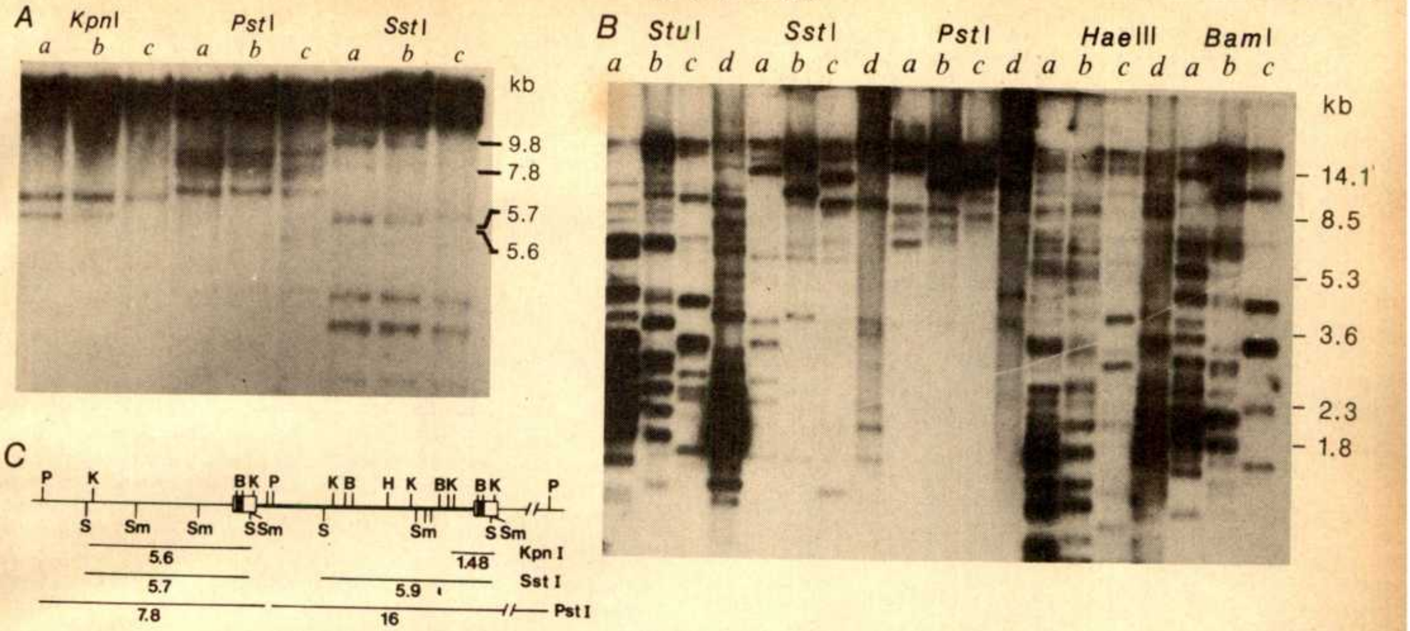

Fig. 1 Restriction map and cloning of the Mov-15 locus. *A*, Isolation of mouse DNA sequences flanking the Mov-15 provirus. A recombinant plasmid, pMov-15/1, containing sequences flanking the provirus, was hybridized to DNAs from homozygous Mov-15 males (lane *a*), heterozygous Mov-15 males (lane *b*) and BALB/c males (lane *c*) digested with the indicated restriction enzymes. *B*, DNA polymorphism at the Mov-15 locus. DNAs from BALB/c (lanes *a*), C57BL/6 (lanes *b*), 129/J (lanes *c*), and SWR/J (lanes *d*) mice were digested with the restriction enzymes shown and analysed by Southern blot analysis as described in *A*, using pMov-15/1 as a probe. *C*, Restriction map of the proviral region. White boxes, LTRs; black boxes, the bacterial *supF* gene; black bar, the proviral genome and the line left and right from the provirus, the flanking mouse sequences. K, P, H, S and Sm denote cleavage sites for *Kpn*I, *Pst*I, *Hin*d III, *Sst*I and *Sma*I, respectively. The map was deduced from restriction enzyme analysis of cellular DNA from homozygous Mov-15 mice. The lengths of internal and flanking fragments hybridizing with the bacterial suppressor gene are indicated in kb below the figure.

Methods. DNAs were purified, digested with the enzyme indicated, separated on a 0.8% gel and transferred to Gene Screen Plus membranes (NEN)[10]. The filters were hybridized to probes labelled to high specific activity by random oligonucleotide priming[26]. Filters were washed in 0.1 × SSC, 0.1% SDS, at 68 °C. As predicted from the map in *C*, hybridization of the pMov-15/1 probe revealed the presence of a 5.6 kb *Kpn*I fragment, a 7.8 kb *Pst*I fragment and a 5.7 kb *Sst*I fragment in Mov-15 mice (lanes *a* and *b*). These fragments were not seen in DNAs from wild-type mice (lane *c*) and the results therefore confirm that pMov-15/1 represents cellular sequences flanking the provirus. The 9.8 kb *Sst*I fragment found exclusively in DNAs from Mov-15 mice (lanes *a* and *b*) most probably represents a flanking cellular fragment from the 3′ end of the provirus which hybridized with pMov-15/1 due to the repetitive nature of the probe. As expected, the intensities of the Mov-15 specific fragments in homozygous animals were about twice that seen in DNA from heterozygous animals (compare lanes *a* and *b*). The 5.7 kb *Sst*I fragment had been cloned by extracting DNA from the liver of a homozygous Mov-15 female mouse, digesting it with *Sst*I and fractionating it in a sucrose gradient. Fractions containing the Mov-15 specific *Sst*I fragments were identified by hybridization with the *supF* gene and ligated to *Sst*I-cleaved λ gtWES arms. After *in vitro* packaging, recombinant phage particles were titred on the sup^+ host LE 392. About 1.5×10^6 plaque-forming units were then plated on the sup^- host MC 1061 p3[12]. Eight plaques were obtained, five of which contained recombinant phages with the 5.7 kb flanking *Sst*I fragment. The remaining three plaques contained recombinant phages with the internal 5.9 kb *Sst*I fragment. This internal fragment was distinguished from the flanking *Sst*I fragment on the basis of an internal *Hin*dIII site at nucleotide 4894 (ref. 27). A recombinant λ phage containing the flanking sequences was cleaved with *Sst*I, the 5.7 kb insert isolated by preparative gel electrophoresis, further digested with *Bam*HI to remove most of the LTR, and the *Bam*HI–*Sst*I fragment comprising about 90 bp of the LTR plus the flanking mouse sequences was subcloned in pUC 19. The resulting plasmid was designated pMov-15/1.

germline, and genetic evidence indicates that the provirus is integrated into the pseudoautosomal region of the sex chromosome. Proviral copies are lost or gained in 7% of male meioses in this strain, and mouse sequences flanking the provirus are tandemly repeated and highly variable. We conclude that unequal recombination events occur with high frequency in the pairing region, possibly because of the presence of repeated sequences.

The derivation of the Mov-15 strain from $\text{M-MuLV}^{\text{sup}}$-infected preimplantation BALB/c mouse embryos has been described previously[10]. Since all Mov-15 animals develop viraemia, the provirus serves as a dominant marker whose expression can be monitored by radioimmunoassay of serum samples[11]. Animals carrying the provirus were also identified by DNA blot analysis, using as a probe the bacterial suppressor gene present in the long terminal repeats (LTRs)[12]. When two Mov-15 males of the N1 generation (obtained from breeding founder male A, ref. 10) were bred with wild-type BALB/c females, about 90% of male offspring and only 10% of female offspring carried the Mov-15 provirus (Table 1). This partial sex linkage suggested that the provirus in these males was located on the Y chromosome and was transferred to the X chromosome in about 10% of the meioses, resulting in 10% viraemic daughters. To test this hypothesis, viraemic N2 females were bred with wild-type BALB/c males. As shown in Table 1, the Mov-15 provirus was transmitted equally to sons and daughters of the N3 generation. When viraemic males of the N3 generation which had received the provirus from their mother were bred with wild-type BALB/c females, partial X-linked transmission of the virus was observed (85% of the N4 daughters and only 19% of the N4 sons carried the virus), as expected if the provirus was carried on the X chromosome of the N2 mothers. Viraemic sons of the N4 generation in turn transmitted the virus in a Y-linked mode to the next generation. The results clearly show that the Mov-15 provirus is transferred from the Y to the X chromosome and back from the X to the Y chromosome in 10–20% of all male meioses (Table 1). A gradient of sex linkage has been established within the human pseudoautosomal region, and the recombination frequency can be used to estimate the position of the locus within this region[9]. Thus, markers at the telomeres recombine with frequencies of 50%, and the recombination rate decreases for more proximal markers. If the same holds true for the mouse pseudoautosomal region, our data localize the Mov-15 proviral

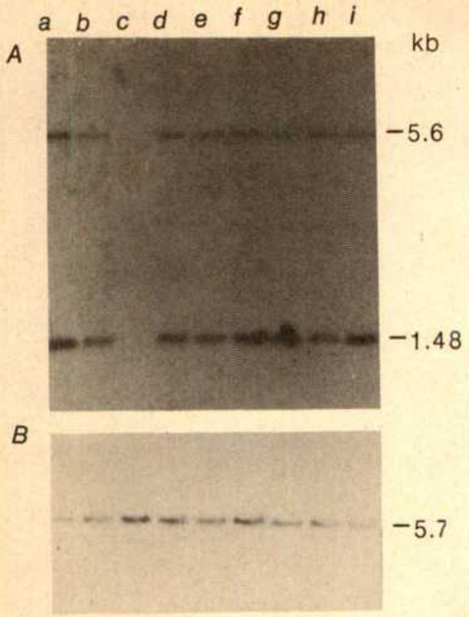

Fig. 2 Unequal recombination at the Mov-15 locus. A homozygous Mov-15 male was mated with a wild-type BALB/c female and embryos were isolated at day 14 of development. DNAs were purified and analysed by blot hybridization following digestion with *Kpn*I (Fig. 1 legend). *A*, Hybridization to πAN7, a plasmid containing the bacterial suppressor gene (gift of H. Huang). The flanking 5.6 kb fragment and the internal 1.48 kb fragment hybridizing to the probe (Fig. 1*C*) are indicated. Since viraemia might lead to the presence of additional proviral copies in the DNA samples, which would all contain the internal fragment, the intensity of the 5.6 kb flanking fragment, which is specific for the provirus inserted in the germ line, was used instead to estimate the number of Mov-15 proviral copies present. *B*, Hybridization with a *Bgl*II–*Hpa*I fragment containing part of the $\alpha 1$(I) collagen gene[28]; the intensity of the 5.7 kb hybridizing fragment serves as a control for the amount of DNA loaded in each lane.

Table 1 Sex-chromosome-linked transmission of Mov-15 provirus

Parents		Offspring			
Inferred genotype F	M	Backcross generation	Sex	Offspring with provirus/total tested	%
wt/wt	Y^{Mov}/X^{wt} (N1)	N2	M	116/130	89
			F	19/191	10
X^{Mov}/X^{wt} (N2)	wt/wt	N3	M	31/57	54
			F	33/51	64
wt/wt	Y^{wt}/X^{Mov} (N3)	N4	M	19/99	19
			F	130/152	86
wt/wt	Y^{Mov}/X^{wt} (N4)	N5	M	43/49	88
			F	14/70	20

All offspring from crosses of Mov-15 males with wild-type BALB/c females were analysed for the presence of virus in the serum by radioimmunoassay using antibodies against p30 (ref. 11). In addition, about 10% of the offspring were analyzed for the presence of proviral sequences by DNA blot hybridization. No discrepancies were observed when the results of both tests were compared. Since virus can be efficiently transmitted by milk from a viraemic mother to her offspring[24], all offspring of Mov-15 females with wild-type BALB/c males (N3) were analysed for the presence of the provirus by blot analysis of tail DNA samples. Among the offspring of the original founder animal (founder A, ref. 10), 3 out of 19 male offspring and 7 out of 27 female offspring contained the Mov-15 provirus. Because of the relatively small number of provirus-carrying offspring, a clear assignment of the provirus in the founder animal to the X or to the Y chromosome could not be made, but two of the three provirus-carrying males were found to have the provirus on the Y chromosome (lines 1 and 2). wt, wild-type; M, males; F, females.

genome to the proximal part of the X–Y pairing region. Three point crosses with distal markers such as the steroid sulphatase gene[3] will allow us to test this hypothesis directly.

In order to analyse the organization of the Mov-15 locus, a probe corresponding to sequences flanking the provirus was isolated by cloning into λgt WES using selection for the *supF* gene (ref. 12; see Fig. 1*A* legend). This probe, designated pMov-15/1, hybridized to differently-sized fragments in virus-positive and virus-negative animals, demonstrating that the cloned sequences represent cellular sequences flanking the Mov-15 provirus (Fig. 1*A*). In addition to the Mov-15 specific fragments, the probe hybridized with variable intensities to many other fragments of different sizes, even under stringent conditions of hybridization and washing. To analyse the flanking sequences further, the insert of pMov-15/1 was digested with *Sma*I and the three fragments produced (Fig. 1*C*) were sub-cloned and used as probes on Southern blots. Each fragment produced identical patterns of hybridization to those shown in Fig. 1*A*. Each fragment hybridized with all the others, confirming that the cellular sequences flanking the provirus are not only repeated many times in the genome, but are also internally repetitive. The repeat length unit is at the most 1.3 kilobases (kb), the length of the smallest fragment tested.

The flanking sequences were also used to probe DNAs from different mouse strains. Hybridization bands of different size and intensity were observed when DNAs from different mouse strains were compared (Fig. 1*B*). This polymorphism was not detected when males and females of the same inbred strain (BALB/c) were compared (data not shown). The sequences are specific for mouse and do not hybridize, even under low stringency, to DNAs from man, hamster, rat, pig and chicken (data not shown). Repetitive and highly polymorphic sequences have been found previously in the human pseudoautosomal region (refs 6–9, and D. Page, unpublished results) as well as on the mouse Y chromosome[13,14].

To derive animals homozygous for virus integration at the Mov-15 locus, heterozygous males carrying the provirus on their Y chromosome were crossed with heterozygous females. The genotypes of offspring were determined by Southern blot analysis using the autoradiographic intensity of the 5.6 kb Mov-15-specific *Kpn*I fragment (representing part of the LTR and 5′ flanking sequences; Fig. 1*C*) to estimate the number of proviral copies present. Animals with two proviruses were classified as homozygous. As predicted, about equal numbers of homozygous and heterozygous sons and of heterozygous and wild-type daughters resulted from this cross; no wild-type sons or homozygous daughters were found (Table 2).

Table 2 M-MuLV genotype of offspring from parents both heterozygous at the Mov-15 locus

	Cross: $F(X^{wt}/X^{Mov}) \times M(X^{wt}/Y^{Mov})$*		
	Genotype of offspring		
	Homozygous	Heterozygous	Wild type
M	18	22	0
F	0	14	18

The genotype of the offspring was determined by Southern blot analysis of tail DNA using the autoradiographic intensity of the 5.6 kb Mov-15 specific *Kpn*I fragment for estimating the number of M-MuLV^{sup} copies present (for details see legend to Fig. 2). wt, wild-type; M, males; F, females.

* The genotype X^{wt}/Y^{Mov} was assigned to the heterozygous males since they transmitted the Mov-15 provirus to about 90% of their male offspring and about 10% of their female offspring when mated with wild-type BALB/c females.

When males homozygous for virus integration were mated with wild-type BALB/c females, only 93% of the offspring were viraemic instead of the 100% expected for normal Mendelian transmission (Table 3). Southern blot analysis using the *supF* gene fragment or a representative M-MuLV as a probe confirmed that non-viraemic animals did not carry the provirus. As an example, Fig. 2 shows the analysis of embryos derived from one such cross. One of the embryos was negative for proviral sequences (lane *c*). No other fragments hybridizing with the *supF* probe were detected, suggesting that the absence of the provirus was not due to homologous recombination involving the LTRs, as such a mechanism of provirus excision should leave a single LTR at the integration site[15]. While the majority of the offspring carried a single Mov-15 provirus, some animals had acquired two copies. This was shown by comparing the intensities of the 5.6 kb *Kpn*I fragments with a unique fragment as an internal standard (see lane *a* in Fig. 2*A*,*B*). Similar analyses of a larger number of embryos showed that about 7% had acquired two proviral copies (Table 3). The frequency of offspring which have lost or gained a proviral copy is therefore almost as high as the overall frequency of recombination between the X and Y chromosomes at the Mov-15 locus.

The results in Table 3 and Fig. 2 suggest that the region of the X and Y chromosomes into which the provirus has integrated can undergo unequal exchange during male meiosis, as indicated by the loss of the provirus on one sex chromosome (provirus negative offspring) and the gain of a second copy on the other sex chromosome (offspring with two proviral genomes). Blot hybridization analyses on pulse field gels demonstrated that restriction sites in cellular sequences flanking the provirus were identical over a distance of 70 kb (data not shown). Thus the recombination events involved large stretches of host sequences and the provirus was not reinserted into an unrelated part of the genome.

The most likely mechanism to explain the gain or the loss of proviral genomes is unequal crossing-over events between sister chromatids or between homologues either during gametogenesis or during meiosis. Such a mechanism would indeed predict that the two classes of offspring, either with no provirus or with two proviral copies, should arise at equal frequencies. To date, no direct genetic information on the occurrence and frequency of unequal crossing-over is available for mammals. The only mechanism known to occur in mammals which formally could result in unequal crossing-over is sister chromatid exchange. The frequency of sister chromatid exchange in spermatogonia has been determined to be less than two per cell for any chromosomes[16], which is therefore orders of magnitude lower than the frequency we have observed for the unequal exchange of the Mov-15 provirus which occurs within a small chromosomal region. The most likely mechanism by which the Mov-15 provirus is deleted or duplicated is therefore unequal crossing-over during meiosis. Because each recombination event at the Mov-15 locus transfers at least 70 kb of sequences flanking the provirus from one sex chromosome to the other, our observations suggest that a high frequency of unequal recombination may be characteristic for the X-Y chromosome pairing region. In addition, the recombination frequencies we have determined in this work have been in male meiosis only. In the human pseudoautosomal region it has been estimated that the rate of recombination is tenfold higher in males than in females[9]. It will therefore be of interest to study recombination as well as unequal crossover frequencies in Mov-15 females.

Table 3 Transmission of Mov-15 provirus

Parents		Offspring carrying:	
		no provirus	two proviruses
F (wt/wt) x M(X^{Mov}/Y^{Mov})	M:	3/76	
	F:	10/115	
	E:	7/109	8/109
	Total:	20/300 (6.7%)	8/109 (7.3%)

Males homozygous for virus integration at the Mov-15 locus were derived as described in Table 2 and mated to wild-type females. Offspring were tested for viraemia at the age of 4–6 weeks. Non-viraemic animals were analysed for the presence of the provirus by blot hybridization of tail DNAs. In addition, the same tail DNAs were analysed for the presence of the M-MuLV specific 5.9 kb and 2.6 kb *Sst*I fragments as described[25]. Embryo DNAs (isolated between day 12 and 14 of gestation) were analysed for the presence of the provirus by blot hybridization and the intensity of the Mov-15 specific 5.6 kb *Kpn*I fragment on autoradiograms was used for estimating the number of M-MuLV copies present (for details see legend to Fig. 2). wt, wild-type; M, males; F, females; E, embryos.

It has been suggested that repetitive sequences can lead to unequal crossover events resulting in contraction or expansion of sequence families[17]. If such a mechanism is responsible for the unequal exchange observed at the Mov-15 locus, it may be possible to generate animals with larger numbers of proviral copies by successive breeding of offspring with newly-acquired Mov-15 proviruses and so allow comparison of unequal crossing-over frequencies in animals after 'expansion' or 'contraction' of the Mov-15 pairing region. To date, unequal recombination has been directly documented in yeast[18-20] and *Drosophila*[21], but never in mammals, although it has been implicated in the evolution of multigene families[22] and satellite DNAs[17,23] and in the generation of autosomal[29] or sex-linked mutant loci[1]. No information has been available until now on the frequency of such events during meiosis. Only the presence of the unique proviral marker has enabled us to measure the frequency of unequal recombination in a DNA region composed of repetitive sequences. Our results suggest that such exchanges may be frequent in regions where chromosomes synapse during meiosis.

We thank Kirsten Haase and Doris Grotkopp for technical assistance, our colleagues for critical comments on the manuscript, and David Page and Tom Gridley for many helpful suggestions. Supported by grants from the Deutsche Forschungsgemeinschaft, the Stiftung Volkswagenwerk, grant HD-19105 from the National Institutes of Health, and by grant PO1-CA38497 from the National Cancer Institute.

In vivo protein–DNA interactions in a glucocorticoid response element require the presence of the hormone

Peter B. Becker, Bernd Gloss, Wolfgang Schmid, Uwe Strähle & Günther Schütz

Institute of Cell and Tumor Biology, German Cancer Research Center, Im Neuenheimer Feld 280, D-6900 Heidelberg, FRG

Transcriptional activation of gene expression by glucocorticoid hormones is mediated by the interaction of hormone–receptor complexes with specific DNA sequences called glucocorticoid responsive elements (GREs) (refs 1–3, see ref. 4 for review). Deletion of this sequence abolishes glucocorticoid induction of transcription[4-8]. According to a current model, activation of the cytoplasmic receptor protein by hormone binding leads to its increased affinity for and translocation to the nucleus[4]. However, recent reports that the oestradiol and progesterone receptors are localized in the nucleus in the absence of steroid[9-11] led us to examine whether the free receptor interacts *in vivo* with its DNA binding site in the absence of hormone binding. We used the genomic footprinting technique[12-15] to show that changes in *in vivo* protein–DNA interactions within the GREs of the tyrosine aminotransferase gene (*TAT*) can be detected only after hormone treatment in hepatoma cells. Such changes are not detected in fibroblast cells, in which the *TAT* gene is not expressed. Many of the changes in dimethylsulphate reactivity observed in the living cell are also found *in vitro* using cloned DNA and a partially purified glucocorticoid receptor.

The GREs of the rat *TAT* gene are located unusually far upstream, at −2.5 kilobases (kb), from the transcriptional start site (Fig. 1). These elements were initially indicated by the appearance of a DNaseI-hypersensitive site following hormone treatment[16] and then identified by gene transfer experiments and DNaseI footprinting using partially purified glucocorticoid receptor complex *in vitro*[17]. Sequence analysis revealed several sequence motifs that fit the established GRE consensus sequence[1,2,4]. In this study we focus on those elements (II and III, Fig. 1) that have been shown to be essential for glucocorticoid induction by gene transfer experiments.

The instability during purification of the glucocorticoid receptor in the absence of ligand has hindered the analysis of its potential interaction with DNA sequences by *in vitro* methods, but the recent development of the genomic footprinting technique[12,15] has made possible the analysis of receptor-DNA interactions *in vivo* in the absence of steroid. Cells of the *TAT*-expressing hepatoma cell line FTO-2B were withdrawn from glucocorticoids by incubation for at least 16 hours in serum-free medium before induction with the steroid dexamethasone for various times. Trypsinized cells suspended in medium were reacted with dimethyl sulphate (DMS) to probe for the reactivity of the N7 position of guanines in the major groove of the DNA helix[15,19,20]. Patterns of guanine (G) residues were obtained using the probe fragment indicated in Fig. 1.

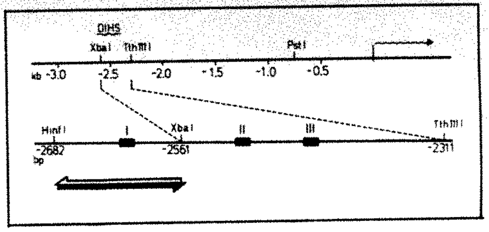

Fig. 1 The 5′-flanking region of the rat *TAT* gene. Upper line, 3 kb of the 5′-flanking region of the rat *TAT* gene: Numbering, distance from the cap-site; wavy arrow, the start of transcription; DIHS, region of dexamethasone-induced DNaseI hypersensitivity[16]. The lower line, enlargement of the region around the dexamethasone-inducible DNaseI-hypersensitive site: black boxes, sequence homologies to the GRE consensus sequence labelled with roman numerals; arrows, single-stranded DNA probes used to generate genomic sequence synthesized from an M13 vector containing the *Hin*fI-*Xba*I fragment.

Figure 2*a* shows an example of such an analysis of uninduced and induced FTO cells. The band intensity reflects the reactivity of a given guanine or a group of unresolved guanines for the chemical modification. Protection from methylation at guanines is most readily explained by protein binding whereas enhanced modification of guanines has been interpreted as a local increase in reagent concentration in a hydrophobic pocket caused by close contacts of protein to DNA[20]. Methylation protection and enhancement after hormone treatment were analysed quantitatively for each guanine (Fig. 2*c*). The data were collected from four independent experiments, each DNA sample being analysed on at least two blots. A number of changes in band intensity appear to be correlated with hormone treatment. DMS protections are evident at the sites of glucocorticoid interaction as identified by DNaseI footprinting[17]. Additional changes in reactivity map to neighbouring sequences (see Fig. 4). In a non-expressing rat fibroblast cell-line (XC cells) no such changes could be discerned after hormone treatment (Fig. 2*a*), nor were they observed when FTO-2B cells were treated with the glucocorticoid antagonist RU486 (Fig. 2*b*).

To ascertain whether the changes in DMS reactivity observed *in vivo* at the *TAT* gene GREs are caused by the glucocorticoid receptor, we performed *in vitro* methylation experiments, using cloned *TAT* DNA fragments containing the GREs and a partially purified glucocorticoid receptor (Fig. 3). The most prominent G protections map to the conserved TGTTCT motif and are identical with those shown to be contacted by the receptor in the GRE of mouse mammary tumour virus (MMTV)[21].

Figure 4 summarizes the data obtained *in vivo* and *in vitro*. Comparison of *in vivo* G reactivity patterns from uninduced and induced FTO-2B cells clearly shows that protection of guanines in the binding site is seen after dexamethasone treatment of cells (Fig. 2). They are accompanied by a number of hormone-induced changes in reactivity in neighbouring sequences. The most dramatically enhanced G reactivities are seen at four adjacent guanines (−2,459 to −2,456) between the two receptor binding sites. Most of the changes in DMS reactivity following hormone treatment are also found *in vitro* using a partially purified glucocorticoid receptor. The changes are not found in XC cells, where the *TAT* gene is not transcribed. These findings strongly indicate that changes in reactivity at guanines within the GRE are indeed caused by interaction of the glucocorticoid receptor with its binding site and that its affinity in the absence of hormone binding is too low to lead to a tight interaction with a GRE at receptor concentrations found in the living cell.

Receptor binding is accompanied by changes in chromatin structure that render a region of 200 base pairs (bp) surrounding the GREs hypersensitive to DNaseI digestion[16]. Whether this altered structure is a prerequisite for receptor binding or rather a consequence of binding is not known. For the MMTV GREs a similar DNaseI hypersensitivity has been shown to precede or parallel hormonal stimulation of MMTV promoter function[18].

It should be emphasized that these effects on guanine reactivities have been observed within a region which is unusually remote (at −2.5 kb) from the cap-site that is selectively rendered hypersensitive to DNase I digestion after dexamethasone treatment. Using the same DNA samples no hormone-dependent DMS effects were seen within several hundred nucleotides surrounding the *TAT* gene cap-site or within a region of DNaseI hypersensitivity at −1,000 bp (data not shown). Within the first

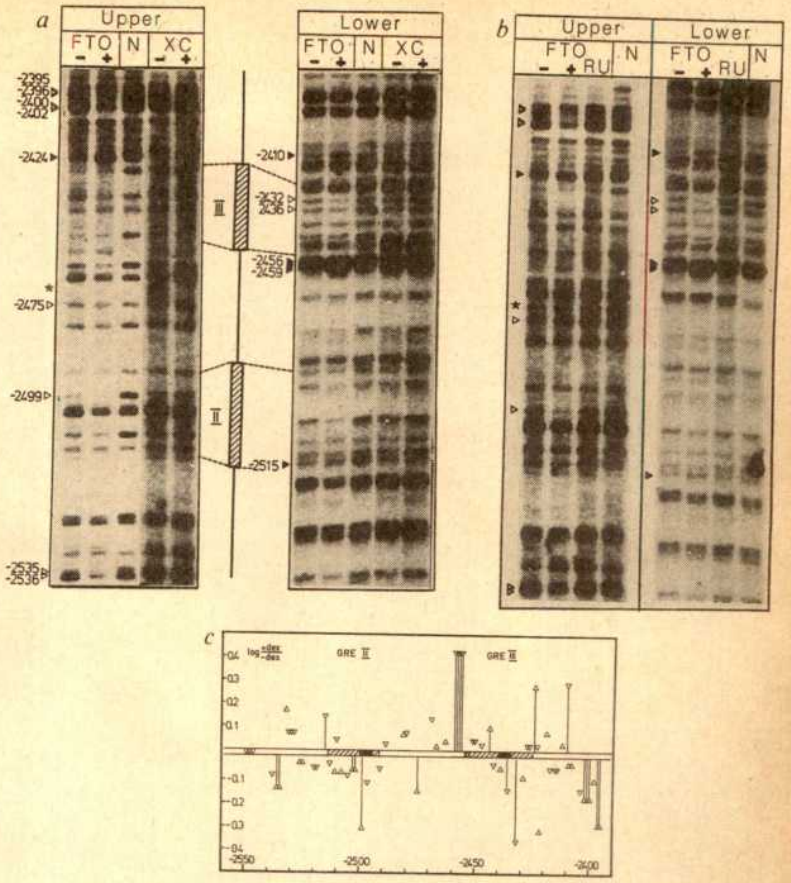

Fig. 2 Glucocorticoid-induced changes in DMS reactivity *in vivo*. *a*, G ladders for both strands of a region of genomic DNA between −2,380 and −2,540 bp (upstream) of the transcriptional start site of the *TAT* gene from DMS-treated FTO-2B or XC cells (+, induced with dexamethasone; −, uninduced); *N*, *in vitro* methylated protein-free DNA. Protection (△) and enhancement (▲) seen when comparing dexamethasone-induced with uninduced FTO-2B cells; numbers, distance from the cap-site. Only those reactivity changes that appeared highly significant in the quantitative analysis (*c*) are indicated. *, Band originating from hybridization to *lacZ* sequences on a contaminating fragment; hatched bars, positions of the two major DNaseI footprints obtained *in vitro* with partially purified glucocorticoid receptor[17]. *b*, As in *a*, but only FTO-2B cells were used and incubation with the glucocorticoid antagonist RU486 (RU) was carried out in parallel with dexamethasone inductions. *c*, Quantitative analysis of hormone-dependent changes in G methylation; summary of results. Nucleotide numbers (from −2,560 to −2,390) upstream of the *TAT* cap-site are given on the abscissa. Hatched bars, sites of receptor binding identified by DNaseI footprinting *in vitro*[17]; black bar, conserved hexanucleotide TGTTCT. For each G residue the logarithm between the median of induced divided by the median of uninduced samples (log +dex/−dex) is plotted. △ and ▽ symbolize this value for each guanine on the upper and lower strand, respectively. Positive values indicate dexamethasone-dependent enhancements, negative values represent inducible protections. The significance of the deviations obtained was checked by comparing induced and uninduced values using a Kruskal-Wallis test[24]. Those values that fell below a threshold of 5% probability of error (1st order error) are indicated with vertical lines.

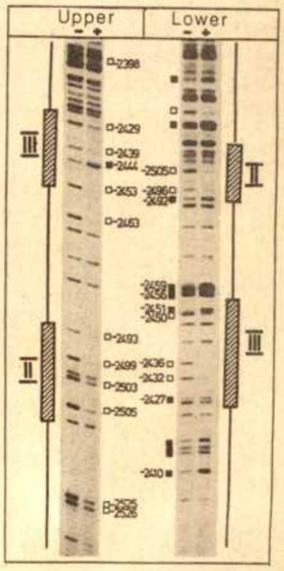
Methods. FTO-2B and XC cells were grown to about 80% confluency in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal calf-serum and 10 mM HEPES *p*H 7.4, withdrawn in serum-free DMEM for at least 16 h and incubated for 4 h with serum-free DMEM with or without 10^{-6} M dexamethasone or 10^{-6} M RU486. Induction times were 20 min–12 h, no significant time-dependent changes in the DMS reactivity pattern were observed (data not shown). DMS treatment of whole cells and *in vitro* methylation of protein-free DNA were as published[15,19]. After isolation of cellular DNA, 25 μg of each sample was restricted with *Hin*fI (Boehringer), reacted with piperidine and separated on a sequencing gel[12]. Details of DNA blotting onto Gene Screen membrane (NEN) UV crosslinking, hybridization and washing of filters were as in ref. 12. Probe synthesis from a single-stranded M13 template was performed as described[12] with modifications: 100 mM NaCls was included in primer annealing and elongation reactions, 250 μCi of [α^{32}P]dATP (NEN), 5,000 Ci mmole^{-1} was used per probe synthesis. The newly-synthesized probe DNA was separated from the template strand in a 6% denaturing gel and recovered from the polyacrylamide by isotachophoresis[22]. Exposure times were 7–14 days with 'lightning plus' intensifying screens (DuPont). Quantitative analysis was done as Giniger *et al.*[23]; four independent DMS treatments of FTO-2B dells were performed under either dexamethasone-induced or uninduced conditions. The resulting DNAs were analysed on at least two independent blots. Genomic sequencing ladders were scanned with an Elscript 400 densitometer (Fisher Scientific) at 16 μm resolution. Peak integrals were calculated and median values determined for each guanine band.

Fig. 3 Changes in DMS reactivity following glucocorticoid receptor binding *in vitro*. Left panel, results obtained for the upper strand and right panel, for the lower strand with (+) and without (−) triamcinolone-saturated glucocorticoid receptor. Protected guanines are indicated by open squares, enhanced methylation at a guanine as a filled square. Guanines that are influenced in their reactivity when comparing the '−' and '+' lanes are labelled with their numbers upstream of the *TAT* cap-site. Hatched bars, regions protected against DNaseI-digestion by bound glucocorticoid receptor *in vitro*[17].

Methods. Purification of the glucocorticoid receptor[25] included as a final step DEAE-Sepharose 6 CL column chromatography in which the receptor eluted as a single peak at 150 mM NaCl. A *Xba*I-*Tth*111I fragment containing both functional GREs was isolated from a subclone and end-labelled using T4 kinase polynucleotide and [γ^{32}P]ATP either at the *Xba*I (upper strand) or at the *Tth*111I (lower strand) sites. Labelled fragment (0.5–1.0 fmol) was incubated with (+) or without (−) 90 fmoles of triamcinolone-saturated receptor in a volume of 25 μl containing 100 mM NaCl, 0.6 mM EDTA, 7% glycerol (w/v), 22 mM Tris-Cl, 1 mM $MgCl_2$, 0.5 μg bovine serum albumin 6 mM β-mercaptoethanol, 0.1 mM dithiothreitol, 1 μM triamcinolone, 15% polyethyleneglycol 6000 (Serva), *p*H 8.2. After 45 min at room temperature, 2 μl of 10% DMS (Fluka) was added and reaction stopped after 2 min incubation at room temperature by adding 75 μl buffer containing 400 mM sodium acetate, 140 mM β-mercaptoethanol and 270 μg ml^{-1} transfer RNA. DNA was extracted with phenol/chloroform (1:1), precipitated and subjected to piperidine cleavage according to Maxam and Gilbert[19], and finally dissolved in formamide containing loading buffer and analysed on a 6% sequencing gel.



200 bp upstream of the transcriptional start site several protections and enhancements can be identified that are strictly correlated with the active state of the gene in FTO-2B cells but are not seen in XC cells. However, none of them are influenced by hormone treatment (P.B., unpublished data).

Comparison of the methylation patterns of the two analysed GREs *in vivo* reveals qualitative and quantitative differences. Whereas the protection of the central guanine (−2,499) in element II is clearly evident, it is less prominent in element III (−2,436). A surprising finding is a very strong protection of a TGT (−2,432) upstream of the conserved hexanucleotide TGTTCT of GRE III. Why the two binding sites behave so differently is not known. Recent results suggest that this difference in DMS reactivities might reflect differences in the

Fig. 4 Summary of results obtained by DMS reactivity experiments *in vivo* and *in vitro*. Changes in DMS reactivity at guanines in the DNA sequence between nucleotides −2,521 and −2,382, upstream of the *TAT* cap-site, are shown. Hatched bars, sites of glucocorticoid receptor interaction as identified by *in vitro* footprinting experiments[17]. Filled symbols, G residues showing enhanced methylation; open symbols, guanines showing protections from methylation. Squares, *in vitro* data; triangles, dexamethasone-dependent changes *in vivo*; half-circles, changes in reactivity found *in vivo* comparing the pattern obtained from uninduced cells with that from protein-free DNA. For the *in vivo* data only those guanines are indicated that by quantitative analysis have been shown to be significantly influenced in their reactivity (Fig. 2*c*).

inducing capacity of the two GREs (M. Jantzen and U.S., unpublished data).

In addition to effects in the receptor binding site, a number of changes in reactivity are observed in neighbouring sequences after dexamethasone treatment. Most prominent among these are the enhancements of guanines at −2,515, −2,459 to −2,456, and at −2,424 and protections of guanines at −2,475, −2,402 to −2,400, −2,396, and −2,395, *in vivo* and to some extent *in vitro*. Whether these changes are due to alterations in DNA structure as a consequence of glucocorticoid receptor binding or interaction with other factors not yet defined remains unclear.

These changes in DMS reactivity are clearly correlated with hormone induction and other changes are evident when the pattern of DMS reactivity of uninduced FTO-2B cell chromatin is compared with that of protein-free FTO-2B DNA (quantitative analysis not shown). Analysis of the reactivity of single guanines in naked genomic DNA at various sites and in plasmid DNA revealed that guanines flanked by thymidines or followed by a thymidine are often unusually sensitive to methylation. This enhanced reactivity is not observed *in vivo*, which might be explained by the difference in reaction conditions inside living cells compared with protein-free DNA *in vitro*. Because of these differences in methylation conditions naked genomic DNA cannot serve as a suitable standard for comparisons of DMS reactivity obtained *in vivo*. The methylation pattern in uninduced FTO-cells is identical to that obtained from induced or uninduced XC-cells. In contrast to observations at the cap-site, there is no evidence for an interaction of protein factors with the receptor binding site in the absence of hormone that discriminates *TAT* in FTO-cells from the gene in nonexpressing fibroblast cells.

We have applied genomic sequencing methodology to obtain information on the *in vivo* interaction of the glucocorticoid receptor with its recognition sequence in the *TAT* gene. Results support the concept that glucocorticoid increases the affinity of the receptor for its target sequence. These experiments do not exclude the possibility that the unliganded receptor can interact with a GRE, albeit with lower affinity and selectivity.

We thank Harry Nick for introducing us to the genomic sequencing methodology; Professor E. Weber for help with quantitative analysis, Alfred Nordheim, Richard Miksicek, Francis Stewart and Michael Boshart for critical reading of the manuscript and M. Cole for secretarial assistance. Steroid-free glucocorticoid receptor binds specifically to mouse mammary tumour virus DNA

Toivo Willmann & Miguel Beato*

Institut für Molekularbiologie und Tumorforschung,
Emil-Mannkopff-Strasse 1, 3550 Marburg, FRG

Steroid hormones are thought to modulate gene expression through their interaction with receptor proteins. The intracellular localization of unoccupied receptor proteins has been a subject of controversy: free glucocorticoid receptor appears to reside in the cytoplasm and moves to the cell nucleus only after binding the steroid[1,2]. The purified hormone-bound glucocorticoid receptor has been shown to bind selectively to hormone regulatory elements (HRE) in the vicinity of hormonally-inducible promoters and, in particular, in the long terminal repeat (LTR) region of mouse mammary tumour virus (MMTV)[3,4]. We have tackled the question of whether the hormone itself is required for the interaction of the receptor protein with the HRE. Using monoclonal antibodies to the receptor we find that upon heat-activation the steroid-free glucocorticoid receptor present in rat liver cytosol binds specifically *in vitro* to the HRE of MMTV. No qualitative differences in the DNaseI-footprints were detected when hormone-free receptor was compared to the hormone-receptor complex or even receptor complexed with the hormone antagonist RU486. We conclude that the steroid ligand is not an absolute requirement for generating the conformation of the glucocorticoid receptor that allows its interaction with the HRE *in vitro*. An alternative function of the hormone *in vivo* could be to modulate nuclear partitioning of the receptor.

To determine whether the steroid ligand is required for specific binding of the receptor to DNA it is important to use receptor that has been subjected to as few manipulations as possible, because the steps required for receptor purification could induce artificial conformational changes of the receptor protein, and thus alter its behaviour in DNA-binding studies. Therefore, we decided to use the receptor in crude hepatic cytosol from adrenalectomized rats. To show that the glucocorticoid receptor in this cytosol is free of ligand we used a competition assay. Cytosol was heated at 100 °C for 4 min to denature the steroid-binding proteins and then extracted with *n*-butanol. The amount of ligand with affinity for the glucocorticoid receptor in the

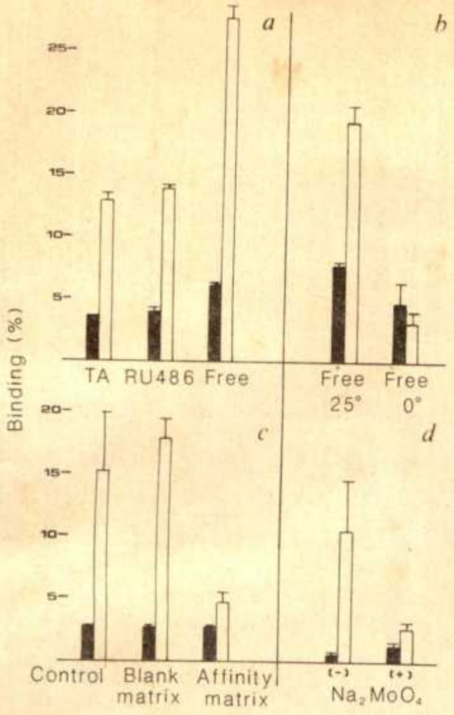

Fig. 1 Immunological detection of DNA-receptor complexes. *a*, DNA-cellulose filtered hepatic cytosol from adrenalectomized rats, either charged with 50 nM [^{3}H]triamcinolone acetonide (TA) or 100 nM RU468 (RU468) or free of hormones (FREE), was activated at 25 °C and aliquots incubated with radioactive DNA fragments derived from plasmid p13-13[6], which contains parts of the *env* gene and the LTR region of MMTV. Monoclonal antireceptor antibodies were added and after incubation precipitated with a second antibody linked to Pansorbin. Bound radioactivity was counted. The average and variation in duplicate measurements are shown. Black bars, binding of a 2.7 kb control fragment (vector sequences and part of the *env* gene), not selectively bound by purified glucocorticoid receptor[4]. Open bars, binding of a 2.3 kb fragment containing the LTR region of MMTV together with mouse genomic sequences and the herpes simplex virus (HSV) *tk* gene. *b*, Left, as in *a* with hormone-free cytosol (25 °C); right, the same but performed at 0 °C during all the incubations to prevent thermal activation (0 °C). *c*, Experiment with uncharged cytosol preincubated at 4 °C for 16 h in presence of 15 vol% of pure Sepharose 4B (Blank matrix), Sepharose 4B containing 0.5 mg ml^{-1} of immobilized dexamathasone (Affinity matrix) or in absence of Sepharose (Control). Shorter DNA fragments were used: black bars, 450 base pairs (bp), *env* and vector sequences; open bars, 600 bp, MMTV-LTR and mouse genomic sequences. *d*, Hormone-free cytosol activated and incubated in the absence (−) or the presence (+) of 20 mM $NaMoO_4$ and with DNA fragments as in *c*.

Methods. Cytosol was passed through DNA-cellulose and receptor content determined by the charcoal technique[5]. Aliquots containing 10 ng of receptor with or without steroid ligand were heat activated at 25 °C for 30 min and incubated for additional 30 min with 10 ng of the end-labelled restriction fragment and 30 ng (with the large restriction fragments, Fig. 1*a*, *b*) or 1 μg (with the short fragments, Fig. 1*c*, *d*) of calf thymus DNA (sheared to an average size of 0.5 kb kilobase (kb) by treatment with 0.3 M NaOH at 100 °C for 30 min) in a final volume of 50 μl containing: 10 mM Tris HCl *p*H 7.5, 0.1 mMm Na_2 EDTA & 110 mM NaCl. After the addition of 50 ng of Protein-A-Sepharose purified monoclonal antireceptor antibody IGR49/4 the incubation was continued at 25 °C for 15 min. The assays were rotated at 4 °C with 1 μl of solid Pansorbin containing 50 μg of purified rabbit anti mouse IgG in a final volume of 200 μl containing: 12 mM HEPES, *p*H 6.8, 150 mM NaCl and at 0.5–1 μg calf thymus DNA. After centrifugation the pellets were washed with Tris-buffer containing 1 mg ml^{-1} bovine serum albumin and 110 mM NaCl.

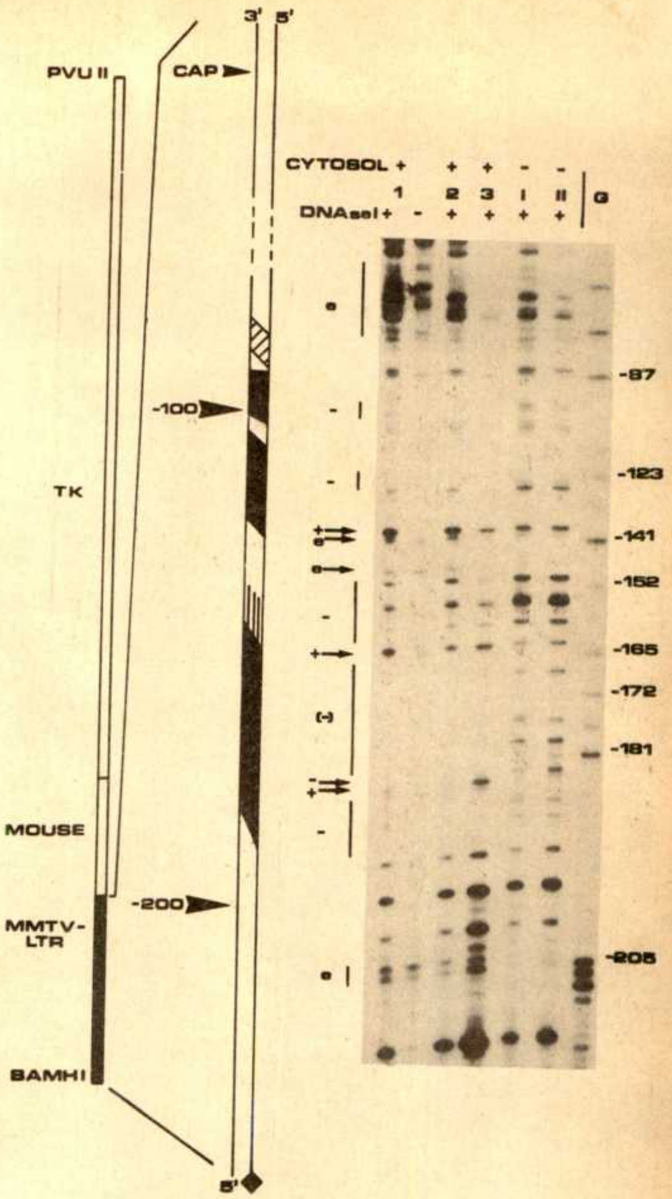

Fig. 2 DNaseI footprints with crude cytosol receptors. DNaseI footprints generated by the receptor complexed with corticosterone (lane 1+), with RU468 (lane 3) or free of hormone (lane 2). Controls: Lane 1−, like lane 1+ but without added DNaseI; lanes I, and II, DNaseI digestions in absence of cytosol. Lane G: guanosine-specific sequencing reaction[19]. The fragment used and position of the label (◆) are shown at the left. −, regions protected by the receptor; +, hypersensitive ones; e, cuts by endogenous nucleases (lane 1−). Numbers refer to the distance from the initiation of transcription (CAP).

Methods. The 2.3 kb fragment of p13-13 was 3′-labelled using dGTP, [α-^{32}P]dATP and the Klenow fragment of DNA-polymerase I. It was used in an assay like that in Fig. 1*a*. The precipitate was resuspended in 80 μl of washing buffer and calf thymus (1 μg) and $MgCl_2$ (final concentration 2.3 mM) in 20 μl were added. After the addition of 0.1 μg DNaseI (Worthington) and incubation at 20 °C for 60 sec the digestion was stopped with 3 μl 250 mM Na_2 EDTA. The DNA was solubilized with 0.6% SDS and 0.3 M NaCl and purified by cooling to 0 °C, centrifugation, fivefold extraction with chloroform/isoamylalcohol and precipitation. After digestion with Pronase P the samples were analysed in a 6.5% polyacrylamide-urea sequencing gel[19]. For lanes I and II 30 ng of labelled DNA were digested in an assay volume of 300 μl with 0.4 μg (I) or 0.9 μg (II) DNaseI.

Table 1 Glucocorticoid receptor ligand in cytosol from adrenalectomized rats

Competitor added		Binding of [^{3}H] triamcinolone acetonide	
Corticosterone	*n*-Butanol extract	c.p.m.	%
—	—	3,215 (154)	100
1 ng	—	1,954 (2)	61
2 ng	—	1,418 (74)	44
5 ng	—	865 (12)	27
25 ng	—	412 (8)	13
—	2 ml	3,468 (247)	108
—	2 ml*	3,140	98

Aliquots of rat liver cytosol from adrenalectomized rats were incubated with [^{3}H]triamcinolone acetonide in the presence of corticosterone or *n*-butanol extract from 2 ml of cytosol. At equilibrium the protein bound radioactivity was determined by the charcoal technique. Values are average and variation of duplicate determinations[5]. To obtain cytosol, male Wistar rats (body weight 180–200 g) were adrenalectomized, maintained under standard conditions with physiological saline *ad libitum* and killed after four days. The livers were perfused through the portal vein with 20 ml cold homogenization buffer (20 mM sodium phosphate, *p*H 7.0, 1 mM Na$_2$EDTA, 50 mM NaCl, 2 mM β-mercaptoethanol, 2 mM dithioerythritol and 10% glycerol), removed, minced and homogenized in three volumes of the same buffer. After centrifugation at 109,000 *g* and 4 °C for 90 min, the supernatant was passed through 0.14 volumes of calf-thymus-DNA-cellulose (0.5 mg DNA per g cellulose). The flow-through was collected and stored in liquid nitrogen. For *butanol extracts*, 2 ml aliquots of cytosol were heated at 100 °C for 4 min, extracted with one volume *n*-butanol by vortexing for 30 s and concentrated by evaporation. A control extraction with charcoal-treated cytosol supplemented with [^{3}H]cortisol (200 ng, 0 °C for 60 min) showed that this procedure extracts 86% of the hormone. For the competition assay, cytosol was treated with 10% dextran-coated charcoal[5] at 0 °C for 5 min, and aliquots (100 μl) were preincubated for 5 min in the presence of either corticosterone or *n*-butanol extract, before addition of 0.9 ng of [^{3}H]triamcinolone acetonide (Amersham Büchler, specific activity 1.1 TBq mmol^{-1}) and further incubation for 60 min at 0–4 °C. The amount of protein-bound radioactivity was determined by the charcoal procedure[5].

* In this experiment the *n*-butanol extract was added only 5 min prior to the charcoal treatment to exclude an effect of the organic extract *per se* on the efficiency of the test.

organic extract was determined by measuring its ability to compete with ^{3}H triamcinolone acetonide for binding to liver cytosol treated with charcoal[5]. In the hepatic cytosol we used there is less than 0.5 ng ml^{-1} of ligand, so that given the association constant of the receptor for corticosterone, at least 98% of the receptor molecules are free of steroid (Table 1). The unoccupied receptor molecules are able to bind steroid, as shown by their retention in a steroid affinity matrix (Fig. 1*c*, below).

For DNA-binding experiments we used two end-labelled restriction fragments of approximately equal size derived from a plasmid carrying the LTR region of MMTV (Fig. 1, ref. 6). The individual fragments were incubated with hormone-free cytosol or with cytosol that was precharged with either the synthetic glucocorticoid triamcinoline acetonide or the potent antagonist RU486[7]. In every case the cytosol was incubated at 25 °C for 30 min before the addition of DNA. The complexes of receptor and DNA were immunoprecipitated with mouse monoclonal antibodies against the receptor, IGR49/4[8], and rabbit antimouse immunoglobulin linked to Pansorbin (Calbiochem). The radioactivity in the precipitates was measured and is expressed as percentage of the total radioactive DNA. In all experiments the restriction fragment containing LTR sequences was immunoprecipitated three to four times more efficiently than the slightly larger vector fragment (Fig. 1*a*). The hormone-free receptor binds specifically to the LTR-fragment, and exhibits a total DNA-binding activity higher than that of the cytosol incubated with either receptor ligand. This result is not influenced by pre-treatment of the cytosol with dextran-coated charcoal (data not shown), nor by using shorter restriction fragments that increase the specificity of DNA binding (Fig. 1*c*, *d*). No significant differences were found between the DNA binding properties of cytosol charged with agonist or antagonist ligands (Fig. 1*a*).

Specific binding to the LTR fragment was dependent upon previous heat activation of the hormone-free cytosol and could be prevented by addition of 20 mM sodium molybdate (Fig. 1*b*, *d*). Binding of the antibody *per se* does not activate the receptor by artificial conformational change (Fig. 1*b*). That the receptor molecules responsible for specific DNA binding in hormone-free cytosol are able to bind steroid was shown by passing the cytosol through an affinity matrix of immobilized dexamethasone[9]. This treatment removes from the cytosol 85% of the steroid-binding activity, eliminates any immunoreactive material in Western blots (data not shown), and dramatically decreases specific DNA binding (Fig. 1*c*). Thus, a steroid-free form of the glucocorticoid receptor is able to bind active hormone and interacts selectively with the LTR of MMTV. These results were confirmed by a nitrocellulose filter binding assay which did not depend on the use of antibodies (data not shown).

To analyse in more detail the interaction of the different receptor forms with the LTR region we performed DNase I footprinting experiments with the immunoisolated protein–DNA complexes. Though the quality of the footprints is not comparable to those obtained with purified receptor, the limits of the region protected against DNase I are the same as those previously reported[4], and do not differ in the footprints obtained with hormone-free cytosol or with liganded cytosols (Fig. 2). Small quantitative differences between the protection in the presence of agonist and antagonist ligands can not be excluded by these results.

We conclude that the hormone-free glucocorticoid receptor in crude rat liver cytosol binds *in vitro* to the same regulatory elements of the MMTV-LTR region that have been shown to mediate hormonal regulation of transcription *in vivo*[3,4,6]. Our results apparently contradict previous reports, based on binding of radioactive steroid-receptor complexes to an excess of calf thymus DNA-cellulose[10,11], that binding of the hormone to the receptor is a prerequisite for the complex to be 'activated' and bind to DNA. We have repeated these experiments and find that the steroid-free receptor can be heat activated and bind to DNA-cellulose, though the extent of binding is only 20–40% of that observed with the hormone-receptor complexes (data not shown). One possible reason for the quantitative discrepancy with the results presented here could be that an excess of calf thymus DNA-cellulose acts as an ionic exchanger rather than a specific ligand for the DNA-binding domain of the receptor. This could also explain the difference between our results and a previous report claiming that, in a DNA-cellulose competition assay, the receptor complexed to the antagonist RU486 binds less efficiently to MMTV-LTR than receptor complexed to agonist[12].

Our results confirm the reequirement for an *in vitro* heat activation step in order for the receptor, whether free or steroid-bound, to bind to the DNA regulatory sequences. At physiological body temperatures receptor activation *in vivo* should be spontaneous. In the absence of hormone the receptor seems to be localized in the cytoplasm, so that some mechanism preventing receptor activity must exist *in vivo*.

It is conceivable that in the absence of hormone the receptor is complexed to other cellular factors or structures that prevent its interaction with the physiological nuclear targets. Candidates for this role are RNA and the 90 kilodalton heat shock protein, which have been found associated with the non-activated form of several steroid receptors[13,14]. The function of the hormone could be to dissociate the receptor from the 'anchoring' structure, and thus to allow its translocation to the cell nucleus. As a novel variation of this concept, the actual function of the hormone may be to induce a conformational change of the receptor that exposes a nuclear translocation signal. Amino acid sequences responsible for nuclear translocation have been identified in several nuclear proteins, and appear to be distinct from the actual DNA-binding site[15,16]. In the absence of the hormone this hypothetical nuclear translocation signal would be masked and the receptor protein would be excluded from the cell nucleus. The possible role of receptor phosphorylation in this remains an intriguing question.

Common to all of these models is the concept that the DNA binding domain of the receptor is functional in the absence of hormone. In the case of oestrogens there is evidence supporting a weak association of the steroid-free receptor with nuclear structures[17,18]. Whether the hormone ligand is required for the activation of gene expression that follows DNA binding could be analysed in appropriate cell-free experiments.

We thank Hannes M. Westphal for the monoclonal receptor antibodies and Pierre Formstecher for the dexamethasone affinity matrix. This work was supported by grants from the Deutsche Forschungsgemeinschaft and from the Fond der Chemischen Industrie.

Molecular cloning and polymorphism of the human immune deficiency virus type 2

François Clavel, Mireille Guyader, Denise Guétard, Mireille Sallé*, Luc Montagnier & Marc Alizon†

We recently reported the isolation of a novel retrovirus, the human immune deficiency virus type 2 (HIV-2, previously named LAV-2), from patients with acquired immune deficiency syndrome (AIDS) originating from West Africa[1,2]. This virus is related to HIV-1, the causative agent of the AIDS epidemic now spreading in Central and East Africa, as well as the USA and Europe (see ref. 3 for review) both by its morphology and by its tropism and *in vitro* cytopathic effect on CD4 (T4) positive cell lines and lymphocytes. But preliminary hybridization experiments indicated that there are substantiated differences between the sequences of the two genomes[2]. Furthermore, the proteins of HIV-1 and HIV-2 have different sizes and their serological cross-reactivity is restricted to the major core protein, as the envelope glycoproteins of HIV-2 are not immunoprecipitated by HIV-1-positive sera[1,2]. We now report the molecular cloning of the complete 9.5-kilobase (kb) genome of HIV-2, the observation of restriction site polymorphism between different isolates, and a preliminary analysis of the relationship of HIV-2 with other human and simian retroviruses.

A series of filter hybridizations of the HIV-2 RNA genome with probes derived from the complete cloned HIV-1 genome, as well as from regions expected to be well-conserved between HIV-1 and 2 (principally from the *gag* and *pol* genes) yielded extremely weak signals, even in conditions of very low stringency hybridization and washing[2]. This made it very difficult to assess by Southern blot analysis the amount of HIV-2 viral and proviral DNA in infected cells. We therefore cloned a complementary DNA (cDNA) to the HIV-2 genomic RNA, to produce a specific hybridization probe. We used the strategy previously developed for the cloning of HIV-1 (ref. 4). An oligo(dT)-primed cDNA first strand was made in the detergent-activated endogenous reaction (using HIV-2 reverse transcriptase) with virions purified from supernatants of CEM cells (a lymphoblastoid $CD4^+$ cell line[5]) infected with the isolate ROD[2] and continuously producing high amounts of HIV-2. A collection of 10^4 M13 recombinant phages was obtained and screened *in situ* with a labelled HIV-2 complementary DNA first strand. As previously done for HIV-1, we looked directly for HIV-2 specific clones, expected to represent an abundant group in the library, but detected only clones corresponding to cellular repetitive DNA. We can now explain this result by the low representation of HIV-2 specific clones in the library (less than 0.5%, compared to the 5–10% obtained in the cloning of HIV-1). Fortunately the high amounts of recombinant DNA produced by M13, its single-stranded nature, and the ability to perform extremely low stringency hybridization (at T_m −42 °C) on replica filters of M13 plaques allowed the successful use of an HIV-1 probe spanning 1.5 kb of the 3′ end of the LAV_{BRU} isolate (Fig. 1*a*) to screen the library. About 50 positive plaques were detected, purified and characterized by end sequencing and cross-hybridizing of the inserts (Fig. 1). The different clones were found to be complementary to the 3′ end of a polyadenylated RNA, having the AATAAA signal about 20 nucleotides upstream of the poly(A) tail, as found in the long terminal repeat (LTR) of HIV-1 (ref. 6). The part of the HIV-2 LTR that we sequenced is only very distantly related to the homologous domain in HIV-1 (Fig. 1*b*). Only ~50% of the nucleotides can be aligned, requiring the introduction of ~100 insertions and deletions. For comparison, the homology of the corresponding domains in HIV-I isolates from USA and Africa is greater than 95%, with no insertions or deletions (M.A., unpublished data).

The largest insert of this group of M13 clones (E2, 2 kb) was used as a probe to demonstrate HIV-2 specificity in a series of filter hybridization experiments. First, this probe could detect the genomic RNA of HIV-2 but not HIV-1 in stringent conditions (Fig. 2*C*,*D*). Second, positive signals were detected in Southern blots of DNA from cells infected with the ROD isolate as well as other isolates of HIV-2 (Fig. 2*A* and Fig. 4*A*). No signal was detected with DNA from uninfected (not shown), or HIV-1 infected cells (Fig. 2*A*) confirming the exogenous nature of HIV-2. In undigested DNA from HIV-2 infected cells we detect principally a species of ~10 kb, probably corresponding to linear unintegrated viral DNA, and a species with an apparent size of 6 kb, probably the circular form of the viral DNA. Conversely, rehybridization of the same filter with an HIV-1 probe under stringent conditions showed hybridization to HIV-1 infected cells only (Fig. 2*B*).

To isolate the rest of the genome of HIV-2, a genomic library in lambda phage L47.1 (ref. 7) was constructed with a partial *Sau*3AI restriction digest of the DNA from the CEM cell line infected with $HIV\text{-}2_{ROD}$. About 2×10^6 recombinant plaques

Fig. 1 Cloned complementary DNA (cDNA) from the genomic RNA of HIV-2; *a*, genetic organization of HIV-1, position of the HIV-1 *Hin*dIII fragment used as a probe to screen the cDNA library, and restriction map of the HIV-2 cDNA clone, E2. B, *Bam*HI; H, *Hin*dIII; Ps, *Pst*I; Pv, *Pvu*II. *b*, partial nucleotide sequence of the LTR of HIV-2. The corresponding region of the HIV-1 LTR[6] was aligned using the Wilbur and Lipman algorithm (window, 10; K-tuple, 7; gap penalty, 3; ref. 14). The U3-R junction in HIV-1 is indicated; poly(A) addition signal and potential TATA promoter regions are boxed.

Methods. HIV-2 virions were purified from 5 litres of supernatant from a culture of the CEM cell line infected with the ROD isolate[2] and a cDNA first strand using oligo(dT) primer was synthesized in a detergent-activated endogenous reaction on pelleted virus resuspended in 1 ml, as described[4]. RNA-cDNA hybrids were purified by phenol-chloroform extraction, and ethanol precipitation. The second-strand cDNA was done by the DNA polymerase I/RNAase H method[15] and blunt-ended with T4 DNA polymerase using a commercial cDNA synthesis kit (Amersham). After attachment of *Eco*RI linkers (Pharmacia), *Eco*RI digestion, and ligation into *Eco*RI-digested dephosphorylated M13 *tg*130 vector (Amersham), a cDNA library was obtained by transformation of the *Escherichia coli* TG1 strain. Recombinant plaques (10^4) were screened *in situ* on replica filters with the 1.5-kb *Hin*dIII fragment from clone J19, corresponding to the 3′ part of the genome of the LAV$_{BRU}$ isolate of HIV-1 (ref. 4), ^{32}P-labelled to a specific activity of 10^9 c.p.m. μg^{-1}. The filters were prehybridized in 5 × SSC, 5 × Denhardt solution, 25% formamide, denatured salmon sperm DNA (100 $\mu g\ ml^{-1}$) at 37 °C, for 4 h and hybridized for 16 h in the same buffer ($T_m - 42$ °C) plus 4×10^7 c.p.m. of the labelled probe (10^6 c.p.m. per ml of hybridization buffer). The washing was done in 5 × SSC, 0.1% SDS at 25 °C for 2 h. 20 × SSC is 3 M NaCl, 0.3 M Na citrate. Positive plaques were purified and single-stranded M13 DNA prepared and end-sequenced[16].

were screened *in situ* with labelled insert from the E2 cDNA clone. Ten recombinant phages were detected and plaque-purified; three of them were characterized by restriction mapping and Southern blot hybridization with the E2 insert and probes from its 3′ end (LTR) or 5′ end (envelope), as well as with HIV-1 subgenomic probes (HIV-1 probes were used under non-stringent conditions). The λ ROD 4 clone is very likely to contain the complete genetic information of HIV-2, as it carries a 9.5-kb insert and is derived from a circular viral DNA. Two other clones, λ ROD 27 and λ ROD 35 are derived from integrated proviruses and carry a LTR and cellular flanking sequences and a portion of the viral coding sequences (Fig. 3*A*).

The relationship of HIV-2 to other human and simian retroviruses will be more precisely determined by the elucidation of the nucleotide sequence of their genomes, but some preliminary conclusions can already be drawn from hybridization experiments. The relative homology of the different regions of the HIV-1 and 2 genomes was determined by hybridization of fragments of the cloned HIV-1 genome with the labelled λROD 4 expected to contain the complete HIV-2 genome (Fig. 3*B*). Even at very low stringency ($T_m - 42$ °C), the hybridization of HIV-1 and 2 is restricted to a fraction of their genomes, principally the *gag* gene (dots 1 and 2), the reverse transcriptase domain in *pol* (dot 3), the end of *pol* and the Q (or *sor*) genes (dot 5) and the F gene (or 3′ ORF) and 3′ LTR (dot 11). The HIV-1 fragment used to detect the HIV-2 cDNA clones contains the dot 11 subclone, which indeed hybridizes well to HIV-2 under non-stringent conditions. Only the signal from dot 5 persists after stringent washing. The envelope gene, but also the region of the *tat* gene and a part of *pol* seem very very divergent. These data, and also the LTR sequeence (Fig. 1*B*), indicate that HIV-2 is not an envelope variant of HIV-1.

We previously observed that HIV-2 is more related to the simian immune deficiency virus (SIV), than it is to HIV-1 (ref. 2). SIV (also designated simian T-cell lymphotropic virus type 3, STLV-3) is a retrovirus first isolated from captive macaques with an AIDS-like disease in the USA[8]. All the SIV proteins, including the envelope, are immunoprecipitated by sera from HIV-2

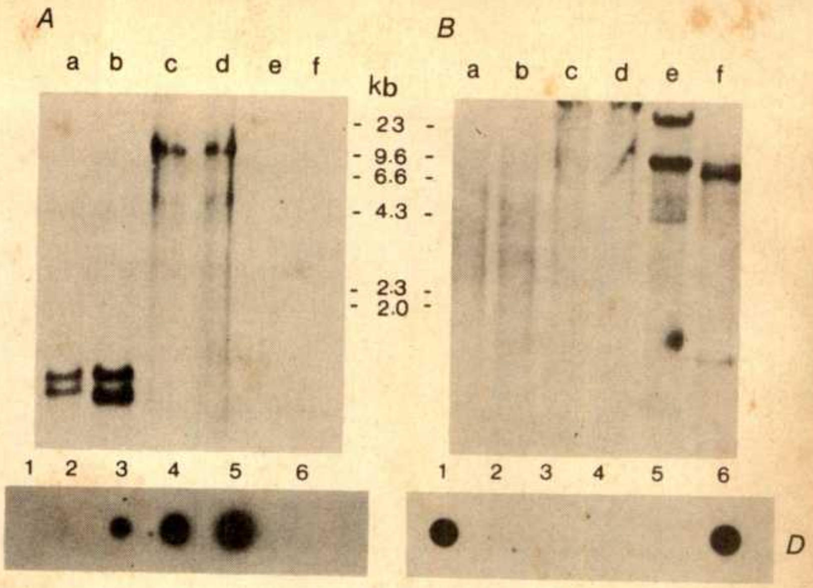

Fig. 2 HIV-2 specificity of the E2 cDNA clone. *A*, *B*, Southern blots of DNA extracted from CEM cells infected with isolates: HIV-2_{ROD} (a, c) HIV-2_{DUL} (b, d) and HIV-1_{BRU} (e, f); a, b, f, *Pst*I digested; c, d, e, undigested. *C*, *D*, dot blot hybridization of pelleted virions from CEM cells infected by the HIV-1_{BRU} (1), SIV isolate Mm 142-83 (3), HIV-2_{DUL} (4), HIV-2_{ROD} (5), HIV-1_{ELI} (6). Dot 2 is a pellet from an equivalent volume of supernatant from uninfected CEM. *A*, *C*, Hybridization with the HIV-2 cDNA (E2); *B*, *D*, hybridization to HIV-1 probe (*Sac*I 9-kb insert from HIV-1_{BRU}, ref. 4).

Methods. DNA was extracted from infected CEM cells continuously producing HIV-1 or 2, and 20 μg of *Pst*I-digested or undigested DNA, was electrophoresed on a 0.8% agarose gel, and transferred to nylon membrane. Virion dot blots were prepared in duplicate as described[2], by pelleting volumes of supernatant corresponding to the same amount of reverse transcriptase activity. Prehybridization was done in 50% formamide, 5 × SSC, 5 × Denhardt's solution, 100 μg ml^{-1} denatured salmon sperm DNA for 4 h at 42 °C. Hybridization was performed in the same buffer plus 10% Dextran sulphate, and 10^6 c.p.m. per ml of the labelled E2 insert (specific activity 10^9 c.p.m. μg^{-1}) for 16 h at 42 °C. Washing was in 0.1 × SSC, 0.1% SDS for 2 × 30 minutes. After exposition (16 h with intensifying screens), the Southern blot was dehybridized in 0.4 M NaOH, neutralized, and rehybridized in the same conditions to the HIV-1 probe labelled to 10^9 c.p.m. μg^{-1}.

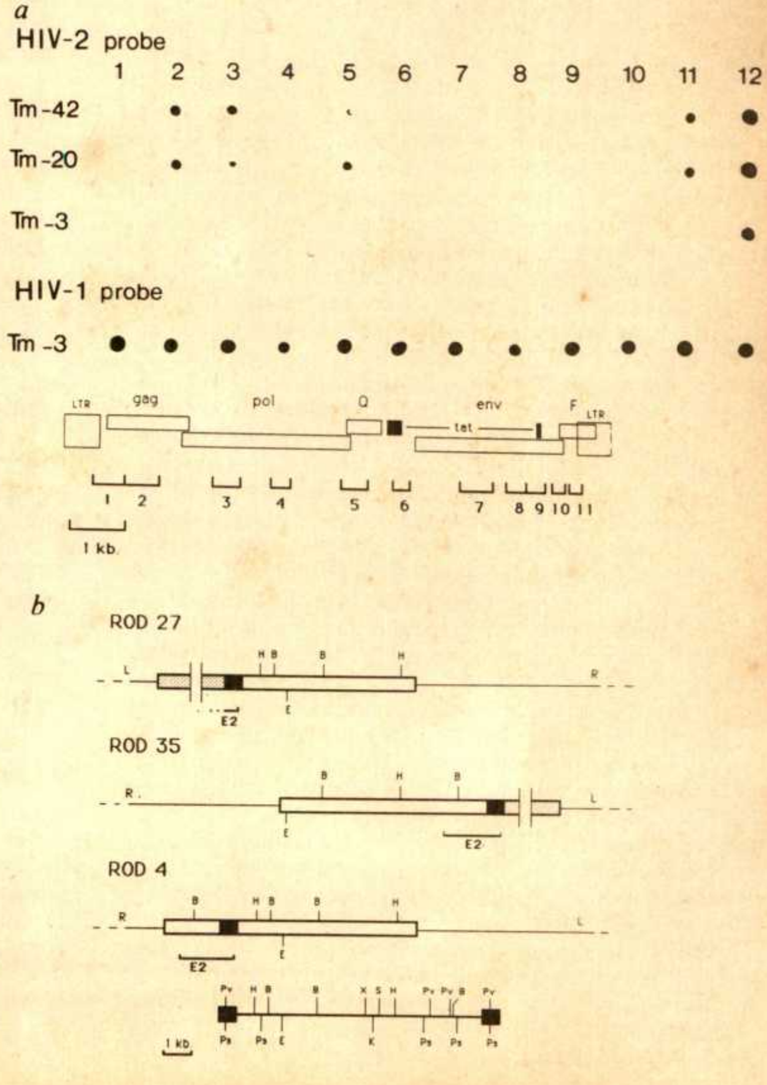

Fig. 3 Restriction map of the HIV-2_{ROD} genomes and similarity to HIV-1. *A*, Organization of three recombinant phage λ clones, ROD 4, ROD 27 and ROD 35; the open boxes represent viral sequence (the LTR are filled), whereas the dotted boxes represent cellular flanking sequences (not mapped); only some characteristic restriction enzymes sites are indicated. ROD 27 and 35 are derived from integrated proviruses whereas ROD 4 is derived from a circular viral DNA. The part of the λ clones that hybridizes to the cDNA E2 is indicated below the maps: a restriction map of the ROD isolate was reconstructed from those of the three λ clones. B, *Bam*HI; E, *Eco*RI; H, *Hin*dIII; K, *Kpn*I; Ps, *Pst*I; Pv, *Pvu*II; S, *Sac*I; X, *Xba*I. R, L, right and left *Bam*HI arms of the λL47.1 vector. *B*, 1–11: dots corresponding to the single-stranded DNA form of M13 subclones from the HIV-1_{BRU} cloned genome. Their size and position on the HIV-1 genome, determined by sequencing[6], is shown below the figure. Dot 12 is a control containing λ phage DNA. The dot blot was hybridized in low stringency conditions (as described Fig. 1) with the complete λ ROD 4 clone as a probe, and successively washed in 2 × SSC, 0.1% SDS at 25 °C. (T_m − 42 °C), 1 × SSC, 0.1% SDS at 60 °C. (T_m − 20 °C), and 0.1 × SSC, 0.1% SDS at 60 °C. (T_m − 3 °C) and exposed overnight. A duplicate dot blot was hybridized and washed in stringent conditions (as described in Fig. 2) with the labelled λJ19 clone carrying the complete HIV-1_{BRU} genome[4]. HIV-1 and HIV-2 probes were labelled at the same specific activity (10^8 c.p.m. μg^{-1}).

Methods. DNA from the HIV-2_{ROD}-infected CEM (Fig. 2, lanes a, c) was partially digested with *Sau*3Al; the 9–15-kb fraction was selected on a 5–40% sucrose gradient, and ligated to *Bam*HI arms of the λL47.1 vector[7]. Plaques (2×10^6) obtained after *in vitro* packaging and plating on *Escherichia coli* LA 101 strain were screened *in situ* with the insert from the E2 cDNA clone. About 10 positive clones were plaque purified, and propagated on *E. coli* C600 recBC. The ROD 4, 27 and 35 clones were amplified and their DNA characterized by restriction mapping, and Southern blotting with the HIV-2 cDNA clone under stringent conditions, and *gag-pol* probes from HIV-1 used under non-stringent conditions.

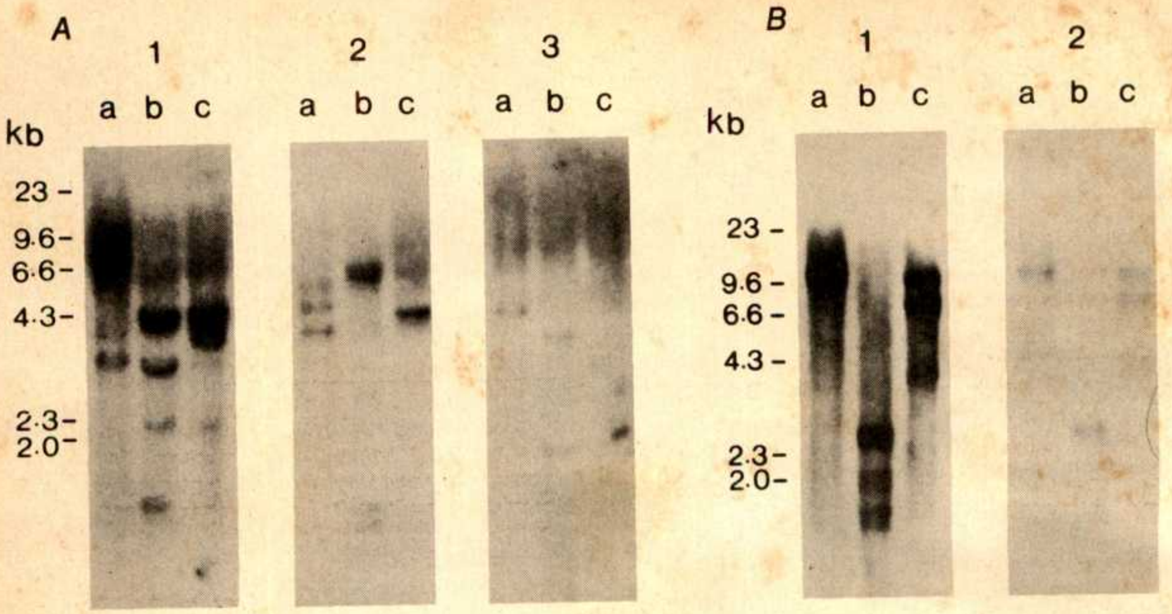

Fig. 4 Restriction map polymorphism in different HIV-2 isolates, and comparison of HIV-2 with SIV. *A*, DNA (20 μg per lane) from CEM cells infected by the isolate HIV-2_{DUL} (panel 1) or peripheral blood lymphocytes (PBL) infected by the isolates HIV-2_{GOM} (panel 2) and HIV-2_{MIR} (panel 3) was digested with: a, *Eco*RI; b, *Pst*I; and c, *Hin*dIII. Note that much less viral DNA is obtained with HIV-2 isolates propagated on PBL. Hybridization and washing were in stringent conditions, as described in Fig. 2, with 10^6 c.p.m. ml^{-1} of each of the E2 insert (cDNA) and the 5-kb *Hin*dIII fragment of ROD 4, labelled to 10^9 c.p.m. $\mu\mathrm{g}^{-1}$. *B*, DNA from HUT 78 (a T lymphoid cell line) cells infected with SIV Mm 142-83; the same amounts of DNA and enzymes were used as for *A*. Hybridization was performed with the same probe as *A*, but in non-stringent conditions, as described (Fig. 1). Washing was for 1 h in 2×SSC, 0.1% SDS at 40 °C (panel 1) and after exposure, the same filter was re-washed in 0.1×SSC, 0.1% SDS at 60 °C (panel 2). The autoradiographs were obtained after overnight exposure with intensifying screens.

infected patients, whereas the serological cross-reactivity of HIV-1 to 2 is restricted to the core proteins[2]. However SIV and HIV-2 can be distinguished by slight differences in the apparent molecular weight of their proteins[2]. In terms of nucleotide sequence, it also appears that the HIV-2 is very close to SIV. The genomic RNA of SIV (provided by Dr R. Desrosiers) can be detected in stringent conditions (Fig. 2*C*) by HIV-2 probes corresponding to the LTR and 3′ end of the genome (E2) or to the *gag* and *pol* genes (data not shown); in the same conditions, HIV-1 derived probes do not detect the SIV genome (Fig. 2*D*). In Southern blots of DNA from SIV-infected cells, a restriction pattern clearly different from HIV-2_{ROD} and other isolates is seen (Fig. 4*B*). All the bands persist after a stringent washing, although the signal is considerably weakened, indicating a sequence homology throughout the genomes of HIV-2 and SIV. It has recently been shown that baboons and macaques could be experimentally infected with HIV-2, providing an interesting animal model for the study of the HIV infection and its preventive therapy (P. Fultz and R. Desrosiers, personnal communication). Attempts to infect non-human primates with HIV-1 have only succeeded in chimpanzees, which are not a convenient model.

We have started a survey of the restriction maps of some of the HIV-2 isolates obtained by our group and from this first study it is already apparent that HIV-2, like HIV-1, undergoes restriction-site polymorphism. Figure 4*A* gives examples of such differences for three isolates, all different one from another and from the cloned HIV-2_{ROD}. It is very likely that these differences at the nucleotide level are accompanied by variations in the amino-acid sequence of the viral proteins, as in the case of HIV-1 (ref. 9).

Recently another group reported the isolation of a human retrovirus from West Africa, apparently highly related to HIV-2, and provisionally named human T-lymphotropic virus type 4 (HTLV-4, ref. 10). This virus displays tropism for $\mathrm{CD4}^+$ cells, and sera from infected patients detect all the HIV-2 proteins (F.C., unpublished data). HTLV-4 has not been isolated from AIDS patients, and therefore has been postulated to be non-pathogenic[10,11]. We feel that this apparent difference in the pathogenicity of HIV-2 and HTLV-4 is due to their means of discovery. That is, HIV-2 was isolated in a survey of AIDS cases in the West Africa, whereas HTLV-4 was found after a large scale serological screening of populations in Senegal for the presence of anti-HIV-1 antibodies and therefore primarily in healthy individual[11]. As HIV-2 and HTLV-4 infect individuals from neighbouring geographical areas, we think that they will fall into the same group of the HIV family.

Another interest in the characterization of HIV-2 is its possible contribution to the delineation of the domain of the envelope glycoprotein responsible for binding to the surface of the target cells and the subsequent internalization of the virus. This interaction was shown to be mediated by the CD4 molecule itself in the case of HIV-1 (refs 12, 13) and similar studies tend to indicate that HIV-2 uses the same receptor[2]. Thus, although there is wide divergence between the *env* genes of HIV-1 and 2, we may find small homologous domains of the envelopes of the two HIV that could represent candidate receptor-binding site. This site could constitute a target for the attempts of raising a protective immune response against this group of retroviruses.

We thank Dr F. Brun-Vézinet, Hôpital Claude Bernard, Paris, and Dr R. Desrosiers, New-England Regional Primate Research Center, for providing us with the HIV-2_{ROD} and SIV Mm 142-83 isolates, Dr Patricia Fultz, Centers for Disease Control, Atlanta, for information on experimental infections with HIV-2, Drs Pierre Sonigo and Simon Wain-Hobson for their interest in that work, and Dr Michael Emerman for critical reading of the manuscript.

A new way of enhancing the thermostability of proteases

Tadayuki Imanaka, Mitsuyoshi Shibazaki & Masahiro Takagi

Department of Fermentation Technology, Faculty of Engineering, Osaka University, Yamada-oka, Suita-shi, Osaka 565, Japan

Thermostability of enzyme can be enhanced by single amino acid substitutions[1,2]. Recent advances in genetic engineering have made it possible to create novel proteins in a predictable manner where structural information for the protein is available. This 'protein engineering'[3] has already been used to enhance enzyme thermostability[4,5], but it is usually not clear which amino acid substitutions should be made We consider that the following approach should be helpful in engineering proteins with enhanced thermostability: highly conserved residues should be left unchanged; the sequences of known mesophilic and thermophilic proteins should be used to suggest the kinds of changes likely to increase thermostability[6]; and substitutions should be made that increase internal hydrophobicity and that stabilize helices for strong internal packing. We describe here the use of this approach to alter the thermostability of the thermostable neutral protease of *Bacillus stearothermophilus*, the sequence of which is known[7,8]. Surprisingly we find that a single mutation that decreases thermostability can require two mutations that increase stability to compensate for it The effects on stability are not additive, suggesting cooperativity.

Comparison of primary structures of enzymes of the same function but different origins is useful to determine the essential regions for activity, because active and/or substrate-binding sites are highly conserved in the homologous regions[9] Amino acid sequences of four neutral proteases from *B stearothermophilus*[8], *Bacillus thermoproteolyticus*[10], *Bacillus subtilis*[11] and *Bacillus amyloliquefaciens*[12] were therefore aligned and compared (Fig 1)

The amino acid sequence of thermostable neutral protease from *B stearothermophilus* was homologous (85%) with that of thermolysin from *B thermoproteolyticus* Similarly, the sequences for thermolabile neutral proteases from *B subtilis* and *B amyloliquefaciens* were also homologous (89%) In contrast, the homology between the thermostable and thermolabile enzymes was lower (~45%) (Fig 1) Nine regions were found to be conserved in all four enzymes These highly homologous regions are likely to be essential for the enzyme activity In fact, it has been reported that His 234 and Arg 206 are the active and substrate-binding sites of neutral protease (or of thermolysin), respectively[13] Zn ion is essential for the enzyme activity of thermolysin, and the three protein ligands for Zn (His 145, His 149 and Glu 169)[13] are conserved in all enzymes (Fig 1) Glu 146, which promotes the attack of a water molecule on the carbonyl carbon of the substrate[13], is also conserved in these enzymes (Fig 1)

Fig 1 Comparison of amino acid sequences of various extracellular neutral proteases Amino acid residues are shown by single letters A, Ala, C, Cys, D, Asp, E, Glu, F, Phe, G, Gly, H, His, I, Ile, K, Lys, L, Leu, M, Met, N, Asn, P, Pro, Q, Gln, R, Arg, S, Ser, T, Thr, V, Val, W, Trp, Y, Tyr A blank indicates the absence of corresponding amino acid of this position Enzyme sources are 1, *Bacillus stearothermophilus*[8], 2, *Bacillus thermoproteolyticus*[10], 3, *Bacillus subtilis*[11], 4, *Bacillus amyloliquefaciens*[12] Homologous sequence regions are surrounded by rectangles Active and substrate-binding sites of thermolysin are indicated by ○ and □, respectively Protein ligands for Zn and Ca ions for thermolysin are indicated above the sequence Substitutions expected to enhance or reduce the thermostability of *B stearothermophilus* protease in comparison with that of thermolysin from *B thermoproteolyticus* are indicated above the sequence by + or −, respectively Vertical arrows, amino acid substitutions in *B stearothermophilus* protease

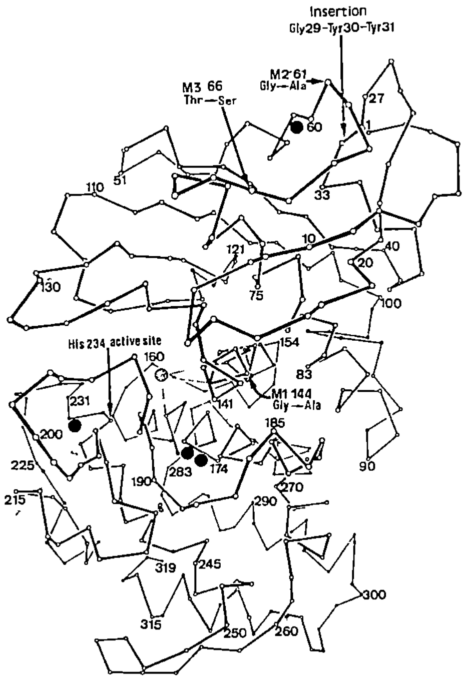

Fig 2 Three-dimensional structure of thermolysin[14] Open circles, α-carbon positions Zinc atom is drawn stippled with its three protein ligands shown diagramatically as broken lines Four calcium atoms are shown as solid circles The amino acid number from the NH_2-terminus is for *B stearothermophilus* neutral protease, originally, Gly-Tyr-Tyr at positions 29-31 are absent in thermolysin

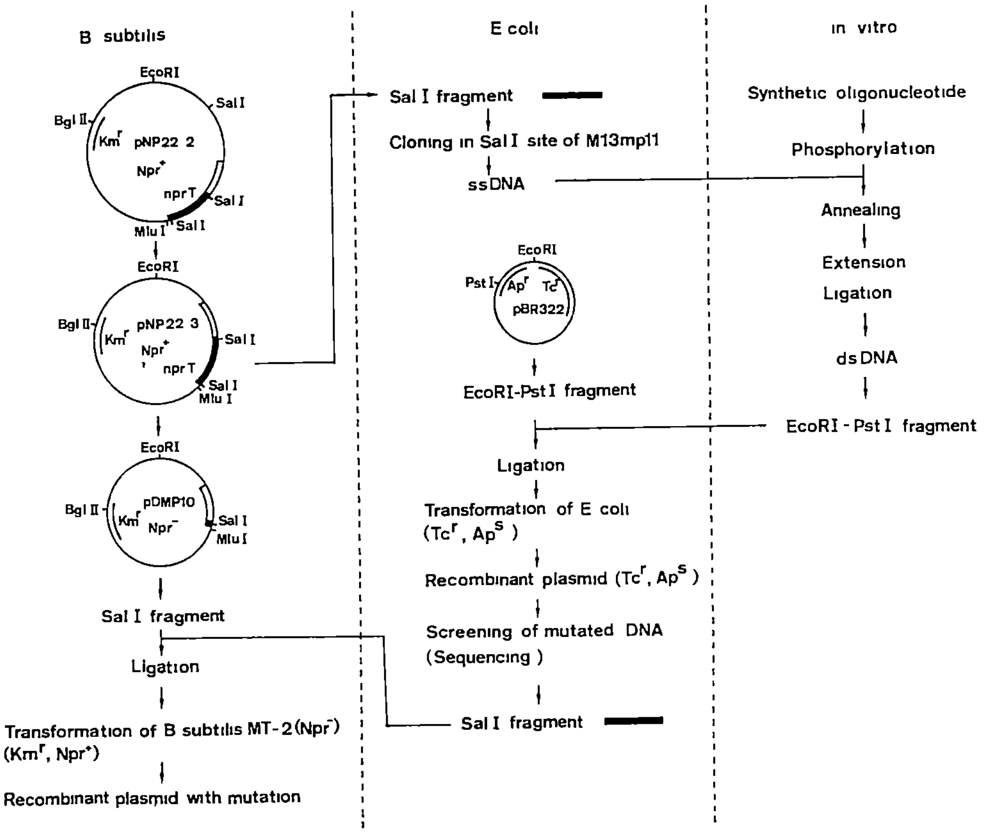

Fig 3 The scheme of site-directed mutagenesis and DNA construction The *B stearothermophilus nprT*$^+$ gene has been cloned in pNP22-2, which is a deletion derivative of pNP22-1 (ref 8) Since the plasmid contains three *Sal*I sites, one *Sal*I near an *Eco*RI site was eliminated by partial digestion of pNP22-2 with *Sal*I, digestion with Bal31, and ligation The plasmid thus obtained is designated pNP22-3 The 888 base pair (bp) *Sal*I fragment containing most of the extracellular portion of protease was isolated from pNP22-3 (Npr$^+$), and the resulting plasmid (Npr$^-$) was designated as pDMP10 The 888 bp *Sal*I fragment was cloned as described[15] in M13mp11, and single-stranded (ss) DNA was isolated The ss DNA was annealed with a synthetic oligonucleotide whose 5′ end had been phosphorylated with polynucleotide kinase After DNA extension using the primer and ligation, the double-stranded DNA was digested with both *Eco*RI and *Pst*I The *Eco*RI-*Pst*I fragment was ligated with larged *Eco*RI-*Pst*I fragment of pBR322 The ligation mixture was used to transform *Escherichia coli* Recombinant plasmids were isolated from the transformants (Tc^r Ap^s) Mutated DNA was screened by either restriction enzyme treatment (mutated primer 5′-CGTCGTG$\underline{G\overset{*}{C}GC}$ATGAGT-3′, *Hha*I for mutation M1 and 5′-GACC$\underline{GATG\overset{*}{C}}$CGACAACC-3′, *Sfa*NI for mutation M2, asterisks, indicate mismatches and underlined sequences the new restriction site) or colony hybridization[16] and the mutation was confirmed by DNA sequencing The 888 bp *Sal*I fragment with mutation was isolated from the recombinant plasmid, and ligated with *Sal*I treated pDMP10 The ligation mixture was used to transform *B subtilis* MT-2 (Npr$^-$)[7] to Km^r Npr$^+$ *B subtilis* MT-2 carrying the mutant plasmid was used to produce extracellular neutral protease

The comparison of *B stearothermophilus* protease and thermolysin revealed that the amino acid frames were completely matched except for additional three amino acids (Gly-Tyr-Tyr, 29-31) in the enzyme from *B stearothermophilus* (Fig 1) Therefore, the three-dimensional structure of *B stearothermophilus* protease would be basically similar to the known tertiary structure of thermolysin[14] shown in Fig 2 Although His 234 (active site), Arg 206 (substrate-binding site), Leu 205, Glu 193 and Asn 162 are far apart in the primary structure of the enzyme (Fig 1), these amino acid residues are near the active site in the three-dimensional structure (Fig 2) and are completely conserved in the four neutral proteases tested Therefore, alteration of amino acids in the highly conserved sequence should be avoided

We decided the position and species of amino acid to be replaced to give enhanced enzyme thermostability according to the procedure outlined The amino acid substitutions between *B stearothermophilus* protease and thermolysin were examined in the light of statistical data on amino acid substitutions which increase thermostability[6] (Fig 1) Thermolysin and *B stearothermophilus* protease contain some amino acids which promote higher thermostability in the first and the second halves, respectively Therefore, the amino acid substitution in thermostable neutral protease was confined to the first half. The substitution Gly to Ala is available for positions 47, 61 and 144 Since Gly 144 is in the α-helix which combines two domains (Fig 2), the amino acid substitution Gly 144 to Ala 144 (mutation M1) should increase the internal hydrophobicity, stabilize the α-helix and thus improve the thermostability of the protease Since it requires only the addition of a methyl group this replacement minimizes interruption of function or internal residue packing arrangements Another mutation, M3 (Thr 66 to Ser 66) should decrease thermostability of the enzyme Amino acid substitutions were performed by site-directed mutagenesis (Fig 3)

Thermostability of wild-type (WT) neutral protease of *B stearothermophilus* and thermolysin was tested at 75 °C (Fig 4*a*) Thermolysin was more thermostable than the WT protease from *B stearothermophilus* When M1 mutation (Gly 144 to Ala 144, GGG to GCG) was introduced, the M1 enzyme was found to be more thermostable than WT enzyme (Fig 4*a*, *b*) The M3 mutation (Thr 66 to Ser 66, ACC to TCC) was found to produce fairly thermolabile enzyme (Fig 4*b*) The double mutant M13 was constructed, with both the M1 and M3 mutations Surprisingly, M13 enzyme had the same thermostability as M3 When a different thermostability increasing mutation, M2 (Gly 61 to Ala 61, GGC to GCC), was added to M3, the double mutant enzyme M23 showed the same stability as M3 But when both mutations M1 and M2 were introduced into M3, the stability of the triple mutant enzyme M123 recovered to some extent compared to that of M3 (Fig 4*b*) It is interesting that two mutations are required simultaneously to enhance the thermostability of M3 enzyme

The statistical data in ref 6 were obtained from many simultaneous replacements of amino acids between thermophilic and mesophilic enzymes We attempted single amino-acid substitution to test the hypothesis and found that a single substitution does not always enhance thermostability

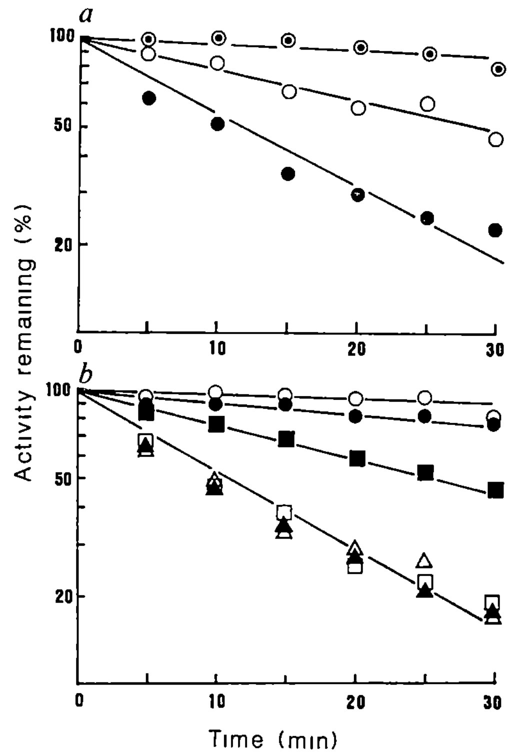

Fig 4 Thermostability of neutral proteases Extracellular protease produced by *B subtilis* carrying $nprT^+$ gene was purified by the method described previously[7] Remaining activity after heating at *a*, 75 °C, *b*, 65 °C was assayed as described earlier[7] and was expressed as the percent of original activity ○, Thermolysin, ●, wild-type enzyme (WT) from *B stearothermophilus*, ○, mutant M1, △, mutant M3, ▲, double mutant M13, □, double mutant M23, ■, triple mutant M123

The thermostability of an enzyme is influenced by many factors, including amino acid sequence, three-dimensional structure, cofactors and *p*H The *Bacillus* neutral proteases require Ca ion as the most important enzyme stabilizing factor Four Ca-binding sites were found in thermolysin (Figs 1 and 2)[14,17] Some Ca-binding sites, Asp 141, Asp 188, Glu 193 and Asp 194 are conserved for all proteases examined (Fig 1) However, a Ca-binding site, Glu 180, of thermostable proteases from *B stearothermophilus* and *B thermoproteolyticus* is deleted in the proteases from *B subtilis* and *B amyloliquefaciens* (Fig 1) This might account for the fact that the latter proteases are rather thermolabile If the amino acid sequence from Thr 177 to Phe 181 were inserted in the *B subtilis* protease, the enzyme would become more thermostable Studies on other mutations using this approach are in progress

We thank S Aiba for valuable discussion and for comments on the manuscript

The protein transcription factor IIIA (TFIIIA) is involved in the synthesis of 5S RNA *in vitro* by RNA polymerase III. It can be isolated from *Xenopus laevis* oocytes as a 7S particle in which the protein is associated with 5S RNA. Recently it has been shown that the native particle contains 7–11 zinc atoms[1]. Analysis of the amino-acid sequence of TFIIIA revealed nine similar domains of approximately 30 amino acids, each containing two invariant pairs of histidines and cysteines, which have been implicated as possible binding sites for the zinc atoms. Other regulatory proteins with sequence homology to the zinc-binding domains of TFIIIA have now been reported[2–4]. Here, we report the results of an EXAFS (extended X-ray absorption fine structure) study of TFIIIA which shows that the coordination sphere of the zinc sites consists of two cysteine and two histidine residues.

EXAFS provides information concerning the number and type of atoms and their bond distances from a metal atom in a metalloprotein[5,6] The limitations of the technique include (1) atoms of similar atomic weight (for example oxygen and nitrogen) cannot be distinguished from one another[7], (2) outer shell distances and number become more unreliable[8], (3) the EXAFS of an atom that occupies several different sites will be an average of all the sites[9] If care is taken in the analysis the technique still offers a means of structural characterization of the local environment of the metal sites The method depends on analysing the oscillations in the absorption or fluorescence spectrum over several hundred electron volts above the metal absorption edge For biological systems where the metal content is usually low, typically ~1–6 mM, very intense X-ray sources are required and synchrotron radiation is ideal in this respect

TFIIIA was isolated as a 7S particle using the procedure of Miller *et al*[1] and the sample was kept in ice before use The protein concentration was ~2 25 mM in zinc by amino-acid analysis assuming that one zinc atom was present in each repeating unit of the protein The intensity of the fluorescence signal in the EXAFS measurement is consistent with this value, so it is probable that all nine sites are occupied by zinc atoms

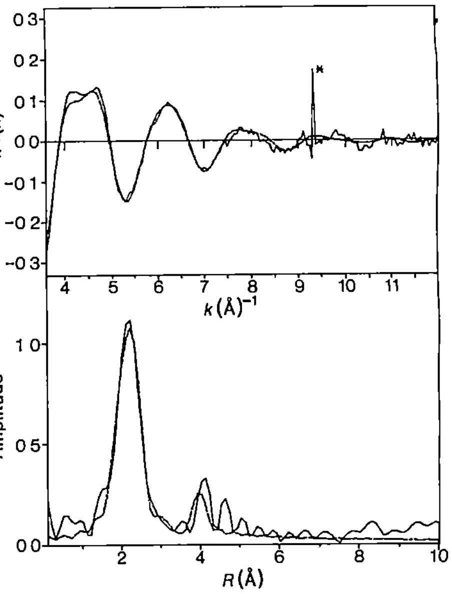

Fig. 1 Zn K-edge EXAFS and Fourier transform of transcription factor IIIA Continuous lines represent the experimental spectra, broken lines the theoretical simulation EXAFS is presented as $k\chi(k)$ plotted against k where k is in Å^{-1} It should also be noted there is a glitch in the spectrum, indicated by asterisk, this is due to other planes in the silicon crystals of the monochromator diffracting and altering the wavelength content of the beam passing through the sample[19] For the EXAFS measurements the protein solution was loaded into a teflon cell, 5 mm thick and 25×30 mm in cross-section in which a window 4×15 mm had been cut, using a syringe The sample was contained between mylar windows $\chi(k)$ is the function describing the oscillations of the EXAFS spectrum, and is multiplied by k to enhance features at high k. k is the momentum of the photoelectron given by $k = [(E - E_0)2m/\hbar^2]^{1/2}$ where m is its mass, E its energy and E_0 the energy of the absorption edge

X-ray absorption spectra were recorded over the energy range corresponding to the zinc K-edge in the fluorescence mode as the fluorescence excitation spectra with individual electronics for each of the four NaI detectors Data were collected at room temperature at the EXAFS station on the Wiggler beam line at the Daresbury Synchrotron Radiation Source operating at an energy of 2 GeV with an average current of 100 mA Harmonic contamination was minimized by using a double-crystal Si 220 monochromator[10] so that the EXAFS oscillations would be accurately measured at each position of the monochromator A total of 28 scans were collected for the TFIIIA and each spectrum was checked individually, and the output from each detector was inspected before averaging Approximately half the spectra were rejected because of odd features and jumps occurring in the data which were not reproducible and the remaining spectra were averaged to produce a single spectrum per TFIIIA with a reasonable signal to noise ratio No radiation damage was observed as no change was seen in the edge of EXAFS between spectra Any change in the local environment as a result of radiation damage would be expected to manifest itself as a change at least in the XANES (X-ray absorption near edge structure) spectrum Data analysis using the single-scattering spherical-wave method for calculating the EXAFS with phase shifts derived from *ab initio* calculations[11–13], the determination of the quality of fit and the refinement were accomplished as described previously[11]

Table 1 Parameters used to simulate the EXAFS associated with the zinc K edge of transcription factor IIIA

	Atom	No	$\sigma^2(\text{Å}^2)$*	$R(\text{Å})$†
1st nearest neighbours	N	2	0 0040	2 00
	S	2	0 0045	2 30
2nd and 3rd nearest neighbours	C	4	0 0125	3 07
	C	4	0 0035	3 88

* σ^2 is a Debye-Waller-like factor and is equivalent to $\Delta R^2_{\text{r m s}}$, the mean square deviation of an atom from its mean position
† The distance of atoms from the zinc atom

Phase shifts and the calculation procedures were checked against a model compound of known crystal structure, zinc II (1,10-phenanthroline)*bis*(4-toluenethiolate)[14] which was collected in transmission mode at the zinc K-edge (model compound supplied by C D Garner, Department of Chemistry, Manchester University) Only the primary co-ordination sphere was used to fit the model The theoretical EXAFS simulation was produced with two nitrogen atoms at ~2 10 Å and two sulphur atoms ~2 25 Å with Debye–Waller type factors (σ^2) of 0 007 and 0 006 (Å^2), compared with the crystal structure average of two nitrogen atoms at 2 112(5) Å and two sulphur atoms at 2 261(2) Å Agreement between the two methods is very good, as the error in fitting the initial shell of atoms for EXAFS is expected to be ≤ ±0 02 Å Thus the reliability of the EXAFS interpretation for the model gave us confidence in the refinement procedure and in transferring the calculated phase shifts to TFIIIA

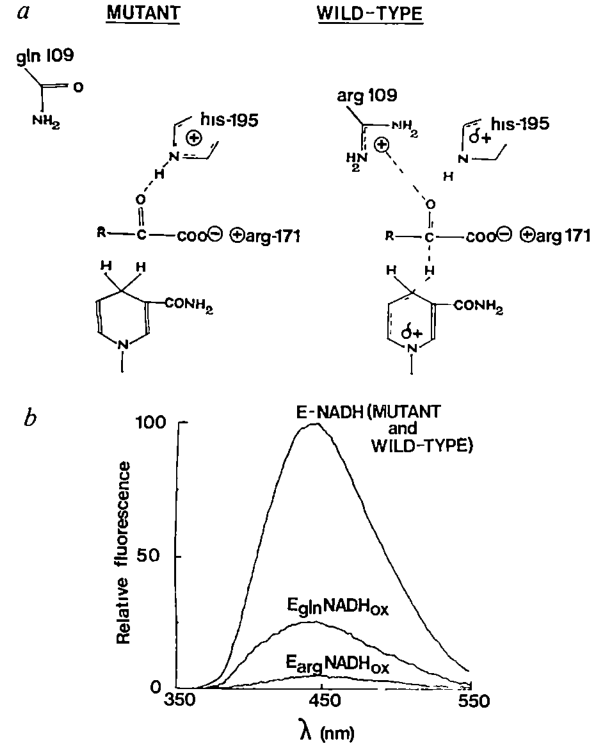

Fig 3 Changes in coenzyme fluorescence on binding oxamate to the enzyme–NADH complex *a*, Proposed structures in the active site of LDH when both NADH and oxamate are bound to the mutant and wild-type enzymes The glutamine amide is further from the substrate carbonyl than the guanidinium group The diagrams emphasize the shift in the electronic structure of the dihydronicotinamide ring in the wild-type enzyme, due to the greater polarization of the substrate carbonyl by arginine 109 Coenzyme fluorescence-emission spectra which reflect this effect[24] are shown in *b* The spectra were taken at an excitation wavelength of 340 nm and the emission was scanned between 350 nm and 550 nm The concentrations of enzyme (subunits), NADH and FBP were 15 μM, 10 μM and 5 mM, respectively and the buffer contained 20 mM triethanolamine-HCl at *p*H 6 The fluorescence enhancement (35%) and blue shift (450 nm to 440 nm at the peak) when NADH bound to the enzyme was the same for the mutant and wild-type binary complexes However, addition of a saturating concentration of oxamate (47 mM) to the mutant enzyme–NADH complex gave a quench of 75% whereas the wild-type complex (in 8 mM oxamate) showed a 95% quench (the coenzyme is five times more fluorescent in the mutant ternary complex)

intrinsic $k_H/k_D = 3$ and a rate of 750 s^{-1} would still give $k_H/k_D = 1$, with a preceding protein-isomerization rate of 250 s^{-1} Thus hydride transfer in the mutant is at least 750/0 6 = 1,200 times slower than in the wild-type enzyme Therefore compared to glutamine, arginine 109 reduces the size of the activation energy barrier for hydride transfer by more than 4 2 kcal

It has been suggested on the basis of crystal structures[1] that arginine 109 destabilizes the enzyme–NADH–pyruvate complex when the loop is closed over the active site, owing to charge repulsion between arginine 109 and the protonated histidine 195 (Fig 1) This predicts that the binding of oxamate in the ternary complex (in which the histidine is protonated and the 98–110 loop is closed[2,16,23]) should be tighter in the mutant enzyme, owing to the absence of charge repulsion from arginine-109 This suggestion is not tenable, since Table 1 shows that the binding of oxamate and pyruvate is weaker the arginine residue stabilizes the NADH-containing ternary complex by 1 6–1 9 kcal This experimental result is consistent with the observation that oxamate (isoelectronic and isosteric analogue of pyruvate) triggers loop-closure in the native enzyme[16] and thus NADH and oxamate bind more tightly when the loop is down

Table 1 Comparison of the properties of native and mutant (Arg-109 → Gln) enzymes

	Native LDH	Mutant LDH
(1) K_d NADH	1 5 μM	1 5 μM
(2) K_m pyruvate (unactivated)	2 mM	30 mM
K_m pyruvate (activated)	0 04 mM	1 0 mM
Activation factor (pyruvate)	50	30
(3) k_{cat}	250 s^{-1}	0 6 s^{-1}
(4) K_d oxamate (unactivated)	1 5 mM	25 mM
K_d oxamate (activated)	0 03 mM	1 mM
Activation factor (oxamate)	50	25
(5) pK of histidine 195 in E–NADH	6 4	6 5
(6) Addition of SO_3 to E–NAD^+		
K_d	4 μM	6 μM
k_{on}	0 94 × 10^5 M^{-1} s^{-1}	1 22 × 10^5 M^{-1} s^{-1}
(7) Thermal stability ($t_{1/2}$ 90 °C)	7 0 min	5 0 min

Unless stated, all parameters were measured at 25 °C in 20 mM triethanolamine-HCl (*p*H6) (1) Measured from NADH fluorescence anisotropy[9] (2) Determined in assay solutions containing saturating (0 2 mM) NADH Activation factor is the ratio of K_m determined in the absence and presence of 5 mM FBP (the allosteric activator)[9] (3) The maximum single-turnover rate at saturating NADH and pyruvate (experimental conditions of Fig 2) (4) Determined fluorimetrically[9] in presence and absence of 5 mM FBP (5) Determined for the bacterial enzyme-NADH complexes (6 μM sites, 5 μM NADH) in 50 mM TEA *p*H 6–8[17] (6) $K_{d(apparent)}$ at *p*H 7 2, 15 μM enzyme sites, 0 5 mM NAD^+, 5 mM FBP k_{on} Is from the variation in first-order rate constant with sulphite (75 μM to 300 μM) in stopped-flow experiments under the same conditions[18] The non-enzymatic rate[19] is 2,400 M^{-1} s^{-1} (7) Temperature stability was measured by incubating the 2 μM enzyme subunits at 90 °C in the presence of 5 mM FBP and assaying the residual enzyme activity

and the arginine residue is in the active site

If the role of arginine 109 is not to destabilize the enzyme–NADH–pyruvate complex, then an alternative means by which it stimulates the rate of hydride ion-transfer must be sought One possibility is that the residue is able to enhance the polarization of the carbonyl group of pyruvate over that achieved by histidine 195 alone (Fig 1) In their pioneering work on LDH, Winer and Schwert[24] suggested that pyruvate and oxamate are able to quench the fluorescence of enzyme-bound NADH by causing a partial transfer of the hydride ion from the nicotinamide C-4 to the substrate C-2 (Fig 3*a*) to generate in the ground state a coenzyme structure which more resembles the unfluorescent NAD^+ The extent of this partial transfer of charge, and resultant fluorescence quench, will depend on the degree of polarization of the substrate carbonyl Figure 3*b* shows the NADH fluorescence spectra in the enzyme–NADH and enzyme–NADH–oxamate complexes of the wild-type and mutant LDHs The result demonstrates that the fluorescence-quench on adding oxamate is far less pronounced in the mutant and provides experimental evidence that arginine 109 increases the polarity of the carbonyl bond of the substrate in the ground state (a function speculated upon by Grau *et al* in a proposed mechanism for pyruvate reduction[1])

An assumption of the 'mutagenesis' approach is that, in making the substitution, there are no widespread and uninterpretable effects on other regions of the protein[25] One control is to determine the three-dimensional structures of the mutant enzyme, but a rapid and more sensitive control is to measure a second catalytic function of the enzyme which is expected to be independent of the mutation LDH catalyses the addition of sulphite (SO_3^{2-}) to NAD^+ in the active site of the enzyme This reaction tests several characteristics of the active site but does not require hydride-ion transfer It depends on histidine 195 being protonated and NAD^+ being activated and orientated to facilitate covalent attachment of the sulphite ion to C-4 of the nicotinamide ring of NAD^+ through a nucleophilic attack[2,18] Table 1 shows the mutant enzyme catalyses NAD-sulphite formation slightly faster than the wild-type in contrast to the >1,200-fold reduction in the rate of hydride transfer Additional evidence that the protein structure is not significantly perturbed by the mutation is its lack of effect upon the temperature stability of the enzyme (Table 1)

In conclusion, the substitution of glutamine for arginine-109 (conserved in all 16 known LDHs and all 4 known MDHs) has changed the properties of the enzyme in a limited but mechanistically interpretable way We suggest that the binding of the anionic pyruvate at the active site neutralizes some of the positive charge in this region, triggering loop closure and exploiting the favourable hydrophobic contacts[2 16] made between the loop and the body of the protein This brings arginine 109 close to the substrate carbonyl (an example of a substrate-induced conformational change) Our data show that the relative enzyme-substrate ground state stabilization of the arginine 109 containing complex, over that containing glutamine, is 1 6–1 9 kcal, while the relative transition state stabilization is 4 2 kcal In the ground state the polarization of the carbonyl bond of the substrate appears to be enhanced by arginine 109 (Fig 3*b*) The greater effect of the loss of arginine 109 on the transition state stability is consistent with the carbonyl bond becoming more polarized as a negative charge develops on the carbonyl oxygen when C-2 goes from sp^2 to sp^3 hybridization

We thank Professor M Buehner for his discussions of the crystallographic structure of *L casei* LDH and the SERC for a project grant (protein engineering), personal fellowship (A R C) and studentship (D B W)

Corrigenda

A complimentary DNA clone for a macrophage-lymphocyte Fc receptor

Victoria A. Lewis, Terry Koch, Helen Plutner & Ira Mellman
Nature **324**, 372–375 (1986)

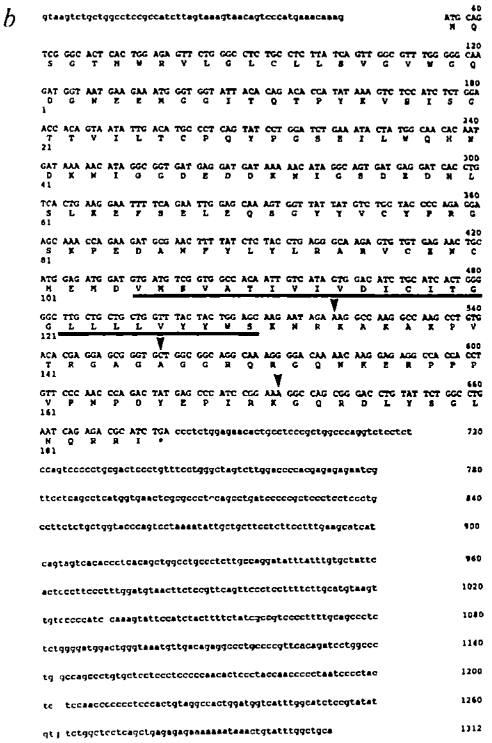
A LATE correction to Fig 1*b* in this letter was omitted The nucleotide numbering for pFcRAb should read 805–1421, not 805–1385 as shown The figure appears correctly on reprints The insert is of 6/6 base pairs, not 580 as in paragraph 2 of the letter

---

Isolation of cDNA clones encoding the 20K non-glycosylated polypeptide chain of the human T-cell receptor/T3 complex

Daniel P. Gold, Jennifer M. Puck, Carolyn L. Pettey, Mildred Cho, John Coligan, James N. Woody & Cox Terhorst
Nature **321**, 431–434 (1986)

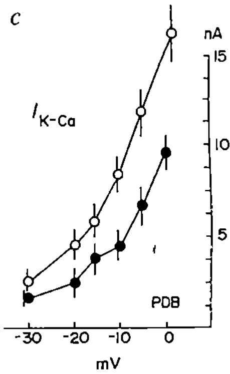
THREE sequencing errors have been found in the human T3-ε nucleotide sequence published in Fig 3*b* These errors have been corrected in the sequence shown below at the positions indicated by vertical arrows The putative transmembrane region is underlined The predicted amino acid sequence ends after residue 185 instead of the reported residue 211

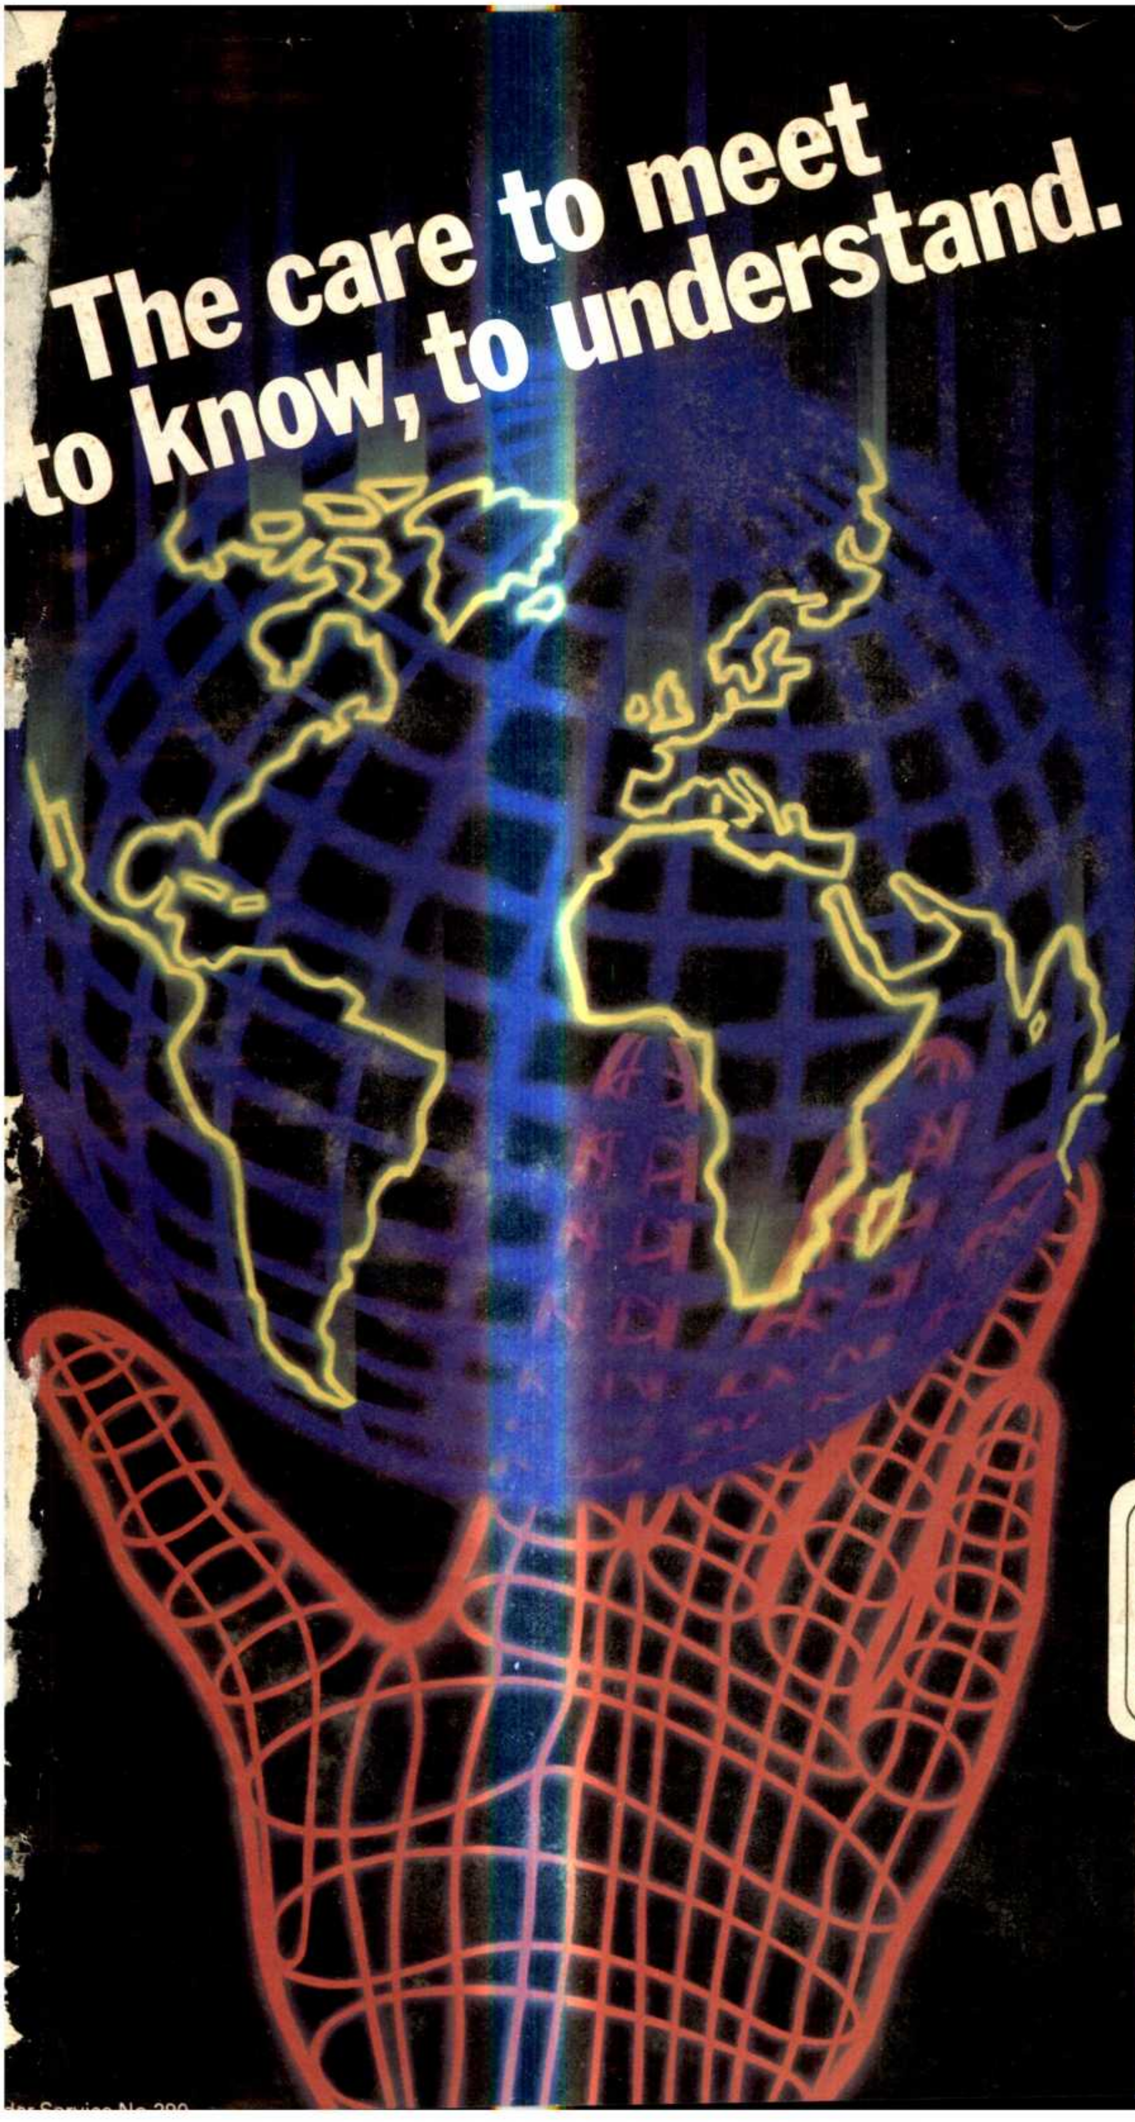


Protein kinase C activation induces conductance changes in *Hermissenda* photoreceptors like those seen in associative learning

J. Farley & S. Auerbach
Nature **319**, 220–223 (1986)

PANEL *c* in Fig 3 of this letter was incorrectly drawn With the ordinate scale corrected the figure reads





Ares-Serono Symposia is an independent foundation, created 1971, to promote scientific research in all disciplines which contribute towards improving human health.
This aim is pursued by means of congresses, courses, seminars and specialized studies.

Some of the international meetings scheduled for 1987 are:

Herpes and Papilloma Viruses
Milan, Italy / March 26-27
Scientific Organization: F. De Palo (I), F. Rilke (I) and H. Zur Hausen (D)
IV Pan American Congress of Androlog
São Paulo, Brazil / May 4-6
Scientific Organization: A. Negro-Vilar (USA) and M. P. De Castro (BZ)
Inhibin - Non-Steroidal Regulation of Follicle Stimulating Hormone Secretio
Tokyo, Japan / May 21-22
Scientific Organization: H. Burger (Aus) an M. Igarashi (J)
Development and Function of the Reproductive Organs
Turku, Finland / June 10-12
Scientific Organization: M. Parvinen (SF)
IV Colloquium of the European Pineal Study Group
Modena, Italy / August 31 - September 4
Scientific Organization: G.P. Trentini (I), A. Oksche (D) and P. Pévet (F)
Cell-to-Cell Communication in Endocrinology
Florence, Italy / October 8-9
Scientific Organization: L. Martini (I), M. Serio (I) and C.W. Bardin (USA)
Differentiation Therapy for Cancer
Tucker's Town, Bermuda / October 23-2
Scientific Organization: G.B. Rossi (I), F. Takaku (J) and S. Waxman (USA)

cDNA Synthesis Kit from Boehringer Mannheim

the time & money saving alternative

cDNA Synthesis Kit, Cat. No. 1013 882
contains all reagents ready for use
for the transcription of 50 µg poly (A)$^+$RNA into cDNA

Get the detailed protocol from your local representative or

boehringer mannheim
